The Vindhyan sedimentary succession in central India spans a wide time bracket from the Paleoproterozoic to the Neoproterozoic period. Chronostratigraphic significance of stable carbon and oxygen isotope ratios of the carbonate phase in Vindhyan sediments has been discussed in some recent studies. However, the subtle controls of facies variation, depositional setting and post-depositional diagenesis on stable isotope compositions are not yet clearly understood. The Vindhyan Supergroup hosts four carbonate units, exhibiting a wide variability in depositional processes and paleogeography. A detailed facies-specific carbon and oxygen isotope study of the carbonate units was undertaken by us to investigate the effect of these processes and to identify the least altered isotope values. It is seen that both carbon and oxygen isotope compositions have been affected by early meteoric water diagenesis. The effect of diagenetic alteration is, however, more pronounced in case of oxygen isotopes than carbon isotopes. Stable isotope compositions remained insensitive to facies only when sediments accumulated in a shallow shelf setting without being exposed. Major alteration of original isotope ratios was observed in case of shallow marine carbonates, which became exposed to meteoric fluids during early diagenetic stage. Duration of exposure possibly determined the magnitude of alteration and shift from the original values. Moreover, dolomitization is found to be accompanied by appreciable alteration of isotope compositions in some of the carbonates. The present study suggests that variations in sediment depositional settings, in particular the possibility of subaerial exposure, need to be considered while extracting chronostratigraphic significance from $\delta^{13}\text{C}$ data.

1. Introduction

Carbon and oxygen isotope data of Precambrian carbonates harbour a wealth of information on past hydrospheres, atmospheres and biospheres (Veizer *et al* 1980, 1999; Beeunas and Knauth 1985). Carbon isotopes have provided a useful tool for correlation of end-Precambrian sedimentary successions of the world (Veizer *et al* 1992; Des Marais 1994; Knoll *et al* 1995; Hall and Veizer 1996; Frank *et al* 1997; Lindsay and Brasier 2000; Shields and Veizer 2002; Ray *et al* 2003). A common assumption of all the studies mentioned above is that both carbon and oxygen isotopes are insensitive

to sedimentary facies (see also Knoll *et al* 1986; Kaufman and Knoll 1995). Carbon and oxygen isotope analyses have been performed on the Proterozoic Vindhyan carbonates and their chronostratigraphic significance have been discussed in many recent studies (Friedman *et al* 1996, 2004; Friedman and Chakraborty 1997; Kumar *et al* 2002; Ray *et al* 2003). Ray *et al* (2003) provided detailed carbon, oxygen and strontium isotope systematics of the Vindhyan carbonates, discussed secular variation of these isotopes and presented primary carbon and oxygen isotope values. Most of these studies recorded average Paleoproterozoic to Neoproterozoic carbon and oxygen isotope values

from the Vindhyan Supergroup. None of the above-mentioned studies, however, discussed isotope compositions of the Vindhyan carbonates in relation to the carbonate facies. Samples for the studies were selected ignoring facies and paleogeography of the constituent carbonate units, which could have influenced isotope compositions. A few studies, however, considered carbonate facies while interpreting the stable carbon and oxygen isotope data (Banerjee 1997; Sarkar *et al* 1998; Chakraborty *et al* 2002; Chakraborty 2004; Banerjee *et al* 2005). Sarkar *et al* (1998) and Chakraborty *et al* (2002) recorded facies sensitivity of Neoproterozoic Bhandar Limestone. In this context, it is appropriate to investigate the depositional and diagenetic controls on stable isotope compositions of the Vindhyan carbonates in detail.

The present paper discusses stable isotope compositions of the Vindhyan carbonates in relation to the sedimentary facies and paleogeography to understand depositional and diagenetic influences on the stable isotope compositions of all the carbonate units of the Vindhyan Supergroup. The study attempts to compare chronostratigraphic versus depositional/diagenetic controls on stable isotope compositions of the Vindhyan carbonates.

2. Geological background and age constraints

The Vindhyan succession of central India is two-tiered, about 4500 m thick and consists of mildly deformed and un-metamorphosed siliciclastics and carbonates exposed over wide areas in central India (figure 1). The Semri Group comprises of

siliciclastics, carbonates and volcanoclastics (figure 2). The Kajrahat Limestone and the Rohtas Limestone are the two important carbonate units of the Semri Group (figure 2). A thin, discontinuous dolomite unit occurs at the mid-level of the predominantly siliciclastic Kheinjua Formation and is known as the Fawn Dolomite. The Upper Vindhyan Group is dominated by clastics and the sole carbonate unit, the Bhandar Limestone occurs near the top of the succession (figure 2). Preservation of delicate sedimentary features is a distinct characteristic of the entire Vindhyan succession. Detailed facies analysis is thus possible on all the carbonate units of the Vindhyan Supergroup. Excellent preservation of sedimentary features, dominantly micritic nature of the carbonate sediments and lack of compaction features rule out significant burial diagenesis of the carbonates (Bose *et al* 2001; Chakraborty 2004). Vindhyan sedimentation took place largely in a shallow marine setting (Chanda and Bhattacharyya 1982; Bose *et al* 2001), although minor paleogeographic shifts have been reported in a few recent studies (Chakraborty 2004; Banerjee *et al* 2005). It is believed that the initial sedimentation took place in an intracratonic rift basin and then a transition to intracratonic sag basin took place during the upper Vindhyan.

On the basis of $^{87}\text{Sr}/^{86}\text{Sr}$ ratios the age of the oldest carbonate unit, namely the Kajrahat Limestone, is assumed to be 1700 Ma old (Ray *et al* 2003). Rasmussen *et al* (2002) and Ray *et al* (2002) determined the age of the overlying Porcellanite Formation to be 1630 Ma by U/Pb SHRIMP dating technique. Sarangi *et al* (2004) determined an age of 1600 Ma age for the Rohtas Limestone. The age of the Fawn Dolomite is, therefore, between 1630

Figure 2. Vertical section showing details of the Vindhyan stratigraphy up to the formation level highlighting the four carbonate units (modified after Bose *et al* 2001). Ages of the carbonate units (after Ray *et al* 2003) are provided on the right of the vertical section.

and 1600 Ma. These data are consistent with those obtained by Rasmussen *et al* (2002) for the ash tuff unit at the base of the Rohtas Formation. The age of the Bhandar Limestone is not precisely determined, but most likely it brackets an age range between 650 and 750 Ma (Ray *et al* 2003).

3. Samples and methods

The constituent facies of the four carbonate units of the Vindhyan Supergroup have been

documented in the Son valley area of Madhya Pradesh through detailed field and petrographic observations carried out over a decade, the results of which have been presented partially elsewhere (Sarkar *et al* 1996, 1998; Banerjee 1997; Bose *et al* 2001; Chakraborty 2004; Banerjee *et al* 2005). In this paper we have presented relatively detailed facies description for the Semri Group as only a few studies provide such information. Fresh samples were collected for isotope analysis from all four of the carbonate units of the Vindhyan Supergroup while noting their respective

Table 1. Facies and paleogeography of the Kajrahat Limestone.

Facies	Description	Interpretation	Representative features
Upper division microbial laminite	Constituted by calcimicrites. Consists of crinkly laminated limestones. Bears V-shaped desiccation cracks. Usually occur at the top of the small stromatolite facies. Towards the top of the stromatolite succession the facies becomes abnormally thicker. Otherwise thickness of the facies varies from 5 cm to 40 cm.	Crinkly nature of the laminae resembles microbial laminite. Desiccation cracks indicate emergence.	 (match-stick length = 2.5 cm)
Small stromatolite	Consisting of smaller stromatolites with average height 3–5 cm and head diameter 2 cm). These usually occur above the larger stromatolites and under the facies G and have axial desiccation cracks. Generally branching in nature and are imbricated. Stromatolite axes imbrication indicates north westerly paleocurrent direction. Average thickness of the smaller stromatolite facies is 16 cm. Constituted by calcimicrites.	Very shallow agitating setting. Desiccation cracks indicates emergence.	 (match-stick length = 2.5 cm)
Large stromatolite	Consisting of larger stromatolites, with average height and head diameter 20 cm and 7 cm. Generally conical in nature (Conophyton), without branching and imbrication. May have axial desiccation cracks. Intercolumnar areas are narrow and filled by small pebble to mud size stromatolite fragments that are selectively dolomitized. Average thickness for the large stromatolite facies is 38 cm. Constituted by calcimicrites.	Greater height and Conophyton affinity indicates deeper paleobathymetry. Desiccation cracks indicates emergence.	 (pen length = 14 cm)

(pen length = 14.5 cm)

Possible allochthonous deposits.

Consists of buff coloured dolostone. Alternates with facies C. They usually have sheet like geometry and sharp base. Average thickness is 4cm. Comprises of subhedral to euhedral non-ferroan dolospars. Pseudomorphs of gypsum rosettes are abundantly present. Typical swallow tale structures are locally recognizable. Despite the general massiveness, thin laminae can be seen under microscope and rosette structures are commonly upright on these planes.

Middle division
sheet bedded
dolomite

(pen length = 14 cm)

Extremely shallow restricted marine setting.

Comprises of dark grey coloured faintly laminated limestone. Thickness of the facies decreases upward from 1.3m to 25cm. Comprises of dolomicrites. Comprises of micritic limestone, locally recrystallised.

Grey limestone

Indicates shallow marine origin of the dolomite body.

Consists of isolated buff-coloured dolostone bodies. These are usually cross-stratified. Average cross-set thickness = 35 cm. Cross-stratifications indicate northwesterly paleocurrent direction. Consists of subhedral non-ferroan dolospars.

Lower division
cross-stratified
dolomite

Massive dolostone

Consists of buff coloured massive dolostone. Sedimentary structures are poorly preserved. Comprises of subhedral non-ferroan dolospars.

Difficult to interpret the depositional setting.

Figure 3. Vertical section showing three divisions of the Kajrahat Limestone in the Son valley area (a). Logs showing constituent facies of the lower division (b), middle division (c) and upper division (d). The given height in b, c and d corresponds to the stratigraphic height from the base of the Kajrahat Limestone. Note cyclicity defined by large stromatolite, small stromatolite and algal laminite in the upper division (d).

facies and stratigraphic position. Samples were selected covering the entire stratigraphy of each of the carbonate units. The samples were collected from different locations in the Son valley area (figure 1). 40 samples were collected from the 255 m thick Kajrahat Limestone section near Kuteshwar area. 26 samples were collected from three sections of Fawn Dolomite around Chorhat, Markundi and Dhanjoria. 31 samples were collected from the Rohtas Limestone section of the Rampur area. 52 samples were collected from several short sections of Bhander Limestone spread over Maihar, Rewa, Aber and Satna and Sajjanpur (figure 1).

Carbon and oxygen isotope analysis of the samples was performed at the Physical Research Laboratory, Ahmedabad. Due care was given to select visibly unaltered micritic carbonate samples

identified by prior petrographic studies involving light microscope and SEM. Thin sections of carbonate samples were stained by Dickson's (1966) method. SEM studies were carried out with the help of JEOL JSM 840A Scanning Electron Microscope at IIT Bombay. Samples containing recrystallisation veins, crack-fills and neomorphic calcites were discarded. Chosen samples were cleaned, disaggregated and then powdered. Carbon and oxygen isotopes ratios were measured by treating the powdered samples with H_3PO_4 at $50^{\circ}C$ for 10 minutes, cleaning the evolved CO_2 from water vapour and other condensable gases and analysing it in a VG Micromass 903 triple collector mass spectrometer. The isotopic ratios $\delta^{13}C$ and $\delta^{18}O$ are expressed with respect to the international standard PDB (Craig 1957) and are reproducible to $\pm 0.1\text{‰}$ at 1σ level. Reproducibility measured

Figure 4. Photographs showing representative features of the Fawn Dolomite: crinkle laminated dolomite (a), tepee structures (b) fenestrae (white patches), (c) and peloids (d). Lens cap diameter = 5 cm, pen length = 14 cm, bar = 0.6 cm.

as 1σ for five samples of NBS-19 ($\delta^{13}\text{C} = 1.95\text{‰}$, $\delta^{18}\text{O} = -2.20\text{‰}$) was approximately 0.1‰ for both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$.

4. Carbonate facies

Summary of facies analysis of the three major carbonate units are presented in tables 1, 2 and 3. A brief discussion on facies and paleogeography of all four of the carbonate units in the study area (sampling sites) is presented below.

4.1 Kajrahat Limestone

The Kajrahat Limestone is up to 255 m thick in the area around Kuteswar and comprises of three superposed divisions characterized by distinctive facies assemblages (Banerjee 1997; table 1, figure 3). The 60 m-thick basal division is predominantly dolomitic and comprises of massive dolomite facies and cross-stratified dolomite facies. The 70 m-thick middle division is composed of vertical alternations of faintly laminated grey limestone facies and buff coloured sheet-bedded dolomite facies. Under the microscope, the sheet-bedded dolomite reveals pseudomorphs of gypsum rosettes. The 125 m-thick upper division predominantly comprises of large stromatolite facies, small stromatolite facies and microbial laminite facies. The larger stromatolite columns often show the presence of axial vertical cracks caused by desiccation

(Bose *et al* 2001). Microscopic observation shows that the cracks are filled up by non-ferroan limpid calcispar. The smaller stromatolites, usually imbricated, occur above the larger stromatolites. Microbial laminites usually occur above the small stromatolites and bear V-shaped cracks filled by clear blocky non-ferroan calcite. Regular vertical stacking of large stromatolites, followed by small stromatolites and microbial laminites indicates the presence of a conspicuous sedimentary cyclicity within the Kajrahat Limestone (figure 3). Banerjee (1997) recorded several such cyclicities from the upper division of the Kajrahat Limestone. Despite their variations in form, all these microbial facies are made of non-ferroan calcimicrite, recrystallized locally into non-ferroan calcite microspar to a variable extent.

Extensive dolomitization has erased many of the primary sedimentary features in the lower division of the Kajrahat Limestone creating difficulty in paleogeographic reconstruction. The large-scale cross-stratified bodies possibly represent channel-fills. Their distribution in the lower and upper divisions suggests a shallow marine environment of deposition. Presence of oriented stromatolites within the upper division corroborates the hypothesis of shallow marine origin (Hoffman 1976). Occasional extreme shallowing is indicated by gypsum crystals in the sheet bedded dolomite facies, presumably formed at the sediment–water interface. V-shaped cracks within the microbial laminite

Figure 5. Vertical section showing constituent facies of the Rohtas Limestone in the Rampur area.

facies represent desiccation cracks and indicate emergence above the water level. The microbial laminite facies possibly formed in very shallow conditions and represents a supratidal setting. Large stromatolite facies, on the other hand, possibly developed in a deep subtidal setting, beneath fair weather wave base (Grotzinger 1986; Southgate 1989). Smaller stromatolites exhibit consistent orientation indicating strong agitation in a shallow subtidal setting (Hoffman 1976; Grotzinger 1986; Glumac and Walker 1997, 2000). Reduction of stromatolite size is related to shallowing of the basin. Therefore, the periodic alternation of large stromatolite, small stromatolites and microbial laminites within the Kajrahat Limestone indicates cyclic fluctuation in sea level leading to eventual exposure

in each cycle. The scale of marine regression was such that it caused repeated exposure of deep subtidal facies (large stromatolite). Obviously, duration of exposure will be more in case of microbial laminites compared to the larger stromatolites.

4.2 Fawn Dolomite

Carbonates occur as discontinuous bodies within the predominantly siliciclastic Kheinjua Formation. In the study area, the carbonate unit is restricted in thin (less than 10 m) local patches without any formal stratigraphic status (Bose et al 2001). The predominantly dolomitic body known as Fawn Dolomite/Salkhan Limestone in the eastern Son valley (Auden 1933; Prakash and Dalela 1982) comprises almost exclusively of microbial laminite (figure 4; Banerjee 1997) and occurs above the progradational fluvio-deltaic succession of the Koldaha Shale (Bose et al 2001). Tepee structures can be seen at places. Fenestrae and bird's eye features can be seen under the microscope (figure 4). Although it consists of laminated non-ferroan dolomicrite, at places (Markundi) it comprises of pelsparite and oosparite (figure 4).

Fenestrae and bird's eye features suggest rotting of microbial mat and subsequent expulsion of microbially generated gases. Tepee structures also suggest collapse of mat cover due to expulsion of gases. The carbonate body sandwiched between siliciclastic strata packages of the Koldaha Shale and the Chorhat Sandstone is considered to be of estuarine origin near Chorhat (Banerjee 1997). The carbonate bodies near Markundi and Dhanjoria possibly have features of lagoonal and supratidal deposits respectively (Banerjee 1997).

4.3 Rohtas Limestone

The Rohtas Limestone gradationally overlies the Rampur Shale in the Son valley area. The latter predominantly consists of black shale with thin limestone interbeds (<3 cm thick). Rohtas Limestone in the Rampur area comprises of six facies (Banerjee et al 2005; figure 5, table 2) described as: black shale facies, ribbon limestone facies, thin-bedded limestone facies, calcarenite facies, flake conglomerate facies and non-edgewise conglomerate facies. Black shale facies alternates with ribbon limestone facies and flake conglomerate facies in the lower parts of the Rohtas Limestone. Middle and upper part of the Rohtas Limestone consist of thin-bedded limestone facies, calc-arenite facies, flake-conglomerate facies and non-edgewise conglomerate facies. Wavy and crinkly laminae are characteristic of the black shale facies (Schieber 1999). The ribbon limestone facies is characterized by alternations of seamed- and non-seamed

bands; dissolution seams are abundant in the seamed band, which appears black while the non-seamed laminae appear white. The frequency of occurrence of dissolution seams decreases upward through a seamed band towards the gradational contact of the immediately overlying non-seamed band; bases of the non-seamed bands are, however, always sharp. The thin-bedded limestone facies is characterized by wave rippled bed tops. The calcarenite facies displays hummocky cross stratification (De Raaf *et al* 1977), climbing ripple laminae and unidirectional cross strata. The flake-conglomerate facies displays conspicuous edgewise fabric exhibited by flake-like carbonate intraclasts. Non-edgewise conglomerate facies displays chaotic arrangement of irregular clasts.

The presence of wave ripples, hummocky cross stratification and edgewise conglomerates in the Rohtas Limestone suggests deposition on the shelf. In the lower part, black shale alternates with dissolution seams bearing ribbon limestone facies, both lacking current features suggesting deep water sedimentation. Upward, the black shale facies is replaced by edgewise conglomerate facies, hummocky cross-stratified and wave rippled limestone indicating overall progradation. Lack of emergence features in these limestones suggests that the water level never became shallow. Ribbon limestone facies represents decoupling of beds into a lower compacted part and an upper uncompacted part; pre-compaction differential cementation has been inferred for the non-seamed bands (Banerjee *et al* 2005).

4.4 Bhander Limestone

Sarkar *et al* (1996) and Chakraborty (2004) have presented a detailed description of the facies and paleogeography of the Bhander Limestone. The ramp-originated Bhander Limestone succession is thought to have developed by forward-backward shifts of shore-parallel facies belts between shoreface and distal offshore. The Bhander Limestone consists of five constituent facies whose depositional regime varied widely ranging from distal offshore to shoreface (table 3, figure 6). Most of the facies are repetitive in nature and appear throughout the succession recording several transitions between offshore and nearshore domains. Amongst the constituent facies the stromatolite facies represents the widest range in paleogeography. Lateral transition of the stromatolite facies with the planar and cross-stratified ones has also been recorded. Sarkar *et al* (1998) and Chakraborty (2004) have recorded basin wide regression leading to exposure at three different levels marked by unconformities and correlative conformities.

4.5 Mineralogical variation across the carbonate facies

Out of the four carbonate units of the Vindhyan Supergroup the Fawn Dolostone is entirely dolomitic. Mineralogical data of the constituent facies of the remaining carbonate units are given in table 1, table 2 and table 3 along with the description of facies. In the study area, the Rohtas Limestone consists predominantly of calcimicrites and calcisiltites (table 2). In Kajrahat Limestone small stromatolite facies, large stromatolite facies, microbial laminite facies and grey limestone facies consist solely of calcimicrites; whereas sheet bedded dolomite facies, cross-stratified dolomite and massive dolomite comprise predominantly of dolomiticrites. In the case of Bhander Limestone the stromatolite facies and planar and cross-stratified facies are predominantly made up of calcite. Plane laminated limestone is, however, dolomitised frequently.

5. Isotope compositions of the carbonate units

5.1 Primary carbon and oxygen isotope values for Paleoproterozoic to Neoproterozoic carbonates

Many workers believe that C-isotopic signatures are usually well preserved in Proterozoic limestones (Knoll *et al* 1986). However, several examples of post-depositional isotopic shifts have been documented in recent years (Kaufmann *et al* 1992; Sarkar *et al* 1998; Ray *et al* 2003). Unfortunately, the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of late Paleoproterozoic and Mesoproterozoic carbonates are not well constrained. Primary or near-original $\delta^{13}\text{C}$ values for the late Paleoproterozoic to early Mesoproterozoic carbonates are found to be within $0 \pm 2\text{‰}$ (Veizer *et al* 1992; Lindsay and Brasier 2000; Shields and Veizer 2002; Ray *et al* 2003). Near-original $\delta^{18}\text{O}$ values of the calcitic carbonates for the entire Proterozoic is estimated to be $-6.5 \pm 1.5\text{‰}$ (Ray *et al* 2003); contemporary dolomites are usually enriched in ^{18}O by $2\text{--}3\text{‰}$ (Land 1980). The primary $\delta^{13}\text{C}$ values of the Neoproterozoic carbonates are believed to be $3 \pm 2\text{‰}$ (Ray *et al* 2003). In the following discussion the isotope ratios of the Vindhyan carbonate samples obtained by us have been compared with the primary range of values suggested by Ray *et al* (2003).

5.2 Kajrahat Limestone

$\delta^{13}\text{C}$ values of 40 samples from different facies of the Kajrahat Limestone were measured and they

Table 2. Facies and paleogeography of the Rohitas Limestone.

Facies	Description	Interpretations	Representative views
Non-edgewise conglomerate	Consists of intraclasts which are chaotically arranged and without grading. The beds have laterally variable thickness (up to 60 cm). Reverse grading may be seen at the base of the beds.	Deposition possibly took place from debris flows of high matrix strength or modified grain flows with internal grain friction. Strong basal shear caused inverse grading.	 (coin diameter = 2.5 cm)
Flake conglomerate	Consists of flake-like carbonate intraclasts (up to 18 cm in length and 2.2 cm in thickness). Clasts are poorly sorted and grading is absent. Edgewise clast fabric is characteristic for the facies.	Episodic nature of the flow is revealed by the occurrence of these clasts in muddy sediments. Strongly erosive storm-driven combined flow is the most likely agent to produce the edgewise conglomerates.	 (coin diameter = 2.5 cm)
Calcarenite	Consists of tabular and sharp-based beds of calc arenite with occasional basal clast concentration. Shows tabular and downslope wedging cross stratifications. Hummocky cross stratifications. Overlying planar laminae are also present. Climbing ripples may occur above planar laminae in a few cases.	Products of episodic storm-originated wave-cum-current combined flow. Waning nature of the flow is evident by the basal clast concentration and planar laminae passing either to small hummocks or wave ripples.	 Hummocky cross stratification (pen length = 14 cm)

Thin bedded limestone	Thin bedded, wave rippled (av. wavelength 7 cm and amplitude 1.5 cm) and consists of calcisiltite.	Shallow water deposition above the fair weather wave base.		Wave ripples (match-stick length = 4.5 cm)
Ribbon limestone	Laterally persistent, alternate dark and white calcimicrite bands. The darker bands contain numerous dissolution seams varying in length from 1 mm to 4.5 cm. The white bands are devoid of seams except at their base. The contact between the seamed and the overlying non-seamed laminae is gradational.	Each couplet comprising seamed laminae and its immediately overlying non-seamed laminae represents products of a single sedimentation phase. Absence of current structures suggests deposition beneath the wave base.		Alternation of seamed (dark, arrowed) and non-seamed laminae (white) (coin diameter = 2.5 cm)
Black shale	Even-bedded, fissile and carbonaceous shales (TOC up to 1.8%) interbedded with thin (<1 cm) micritic limestone laminae. Shale shows wavy laminae, pyrites occur along the carbonaceous laminae.	Calm, quiet and anoxic depositional setting. Outer shelf deposits. Wavy laminae suggests its microbial mat origin.		Black shale-limestone alternation

Table 3. Facies and paleogeography of the Bhander Limestone.

Facies/facies code	Descriptions	Paleogeography
Stromatolite (SM)	Dark-coloured stromatolites of both biohermal and stratiform type. Mostly domal and composite type. Some are of micro-digitate form. Display preferred orientation at places. Commonly associated with PCS and HL. Rarely overlies PLM facies. Consists of non-ferroan calcimicrites.	 (hammer length = 41 cm) Stratiform type indicates very shallow depth. Shallow agitated subtidal setting for digitate stromatolites and inner shelf setting for composite domal forms.
Plane laminated mudstone (PLM)	Grey-coloured lime mudstone alternating with thin siliciclastic muds. Exhibits planar lamination. Thick-thin alternations between calcareous laminae, which at places imparts internal grading. Grades into HL, SH and rarely SM facies. Consists of non-ferroan calcimicrites, frequently dolomitized.	 (pen length = 14 cm) Distal offshore, below storm wave base. Possible spring tide products.
Planar and cross stratified (PCS)	Light coloured, well sorted calc arenite. Locally oolitic and peloidal. Tabular in bed geometry. Planar and cross-stratification common. Exhibits heringbone cross-stratification locally. Polymodal current pattern. Grades into HL, SH and rarely SM facies. Consists of calc-arenite.	 (pen length = 14 cm) Wave- and tide-affected shore face.
Heterolithic (HL)	Exhibits repeated alternation between calcarenite and lime mudstone. Sheet-like bed geometry. Wave ripple and hummocky cross stratifications present internally and gutter cast occur at the soles. Thoroughly dolomitized.	 Storm dominated inner shelf.
Shale (SH)	Greenish grey silty shale, plane laminated; thin limestone/siltstone layers intervene at places. Upward grading into reddish colour silty shale with isolated sand-filled scours.	 Distal offshore close to the storm wave base.

Figure 6. Representative log showing constituent facies of the Bhandar Limestone in the Sajjanpur area.

range from 1.1‰ to −2.5‰ (table 4, figure 7a). $\delta^{18}\text{O}$ values for the same samples vary from −7.9‰ to −13.4‰ (figure 7a). $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ cross-plot reveals conspicuous clusters of data points for individual facies. The sheet-bedded dolomite facies exhibits the highest $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values while the microbial laminite facies exhibits the lowest ones. The average $\delta^{13}\text{C}$ value shifts from low positive (1.0‰ in sheet bedded dolomite facies and 0.3‰ in case of large stromatolite facies) to slightly negative (−0.2‰ in massive dolomite facies and faintly laminated limestone facies, −0.3‰ cross-stratified dolomite facies and −0.4‰ in small stromatolite facies) to still more negative (−1.7‰ in microbial laminite facies). A similar trend is

also observed in the case of $\delta^{18}\text{O}$ values; average $\delta^{18}\text{O}$ value gradually shifts towards more negative values in the same hierarchy from sheet-bedded dolomite facies (−9.3‰ in sheet-bedded dolomite facies, −9.6‰ in larger stromatolite facies, −10.3‰ in smaller stromatolite facies, −10.6‰ in massive dolomite facies and microbial laminite facies, −10.9‰ in faintly laminated limestone facies and −11.7‰ in cross-stratified dolomite facies). Cross-plot of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values shows moderate correlation with values from sheet-bedded dolomite facies and microbial laminite facies occupying two ends of the correlation line while values from other facies near the middle part of the correlation line (figure 7a). It also shows wide scatter of data points for the microbial laminite facies; amongst the microbially originated components of the upper division, the large stromatolite facies exhibits the least scatter and small stromatolite facies exhibits moderate scatter of data points. Amongst the seven carbonate facies sheet-bedded dolomite exhibits least scatter of data points and highest $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values. In the upper division, each of the stromatolite cycles shows this general trend; $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values become more depleted going across from large stromatolite facies to small stromatolite facies to microbial laminite facies. $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values, thus, are unrelated to vertical stratigraphy and found to be dominantly facies-controlled.

Moderate correlation of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values ($r^2 = 0.3$) and wide scatter of the data points of the Kajrahat Limestone possibly suggest alteration of most carbon and oxygen isotope values. Except the microbial laminite facies the $\delta^{13}\text{C}$ values of the remaining facies remain confined within a narrow range (close to 0‰). $\delta^{18}\text{O}$ values of the samples exhibit wide variation. It can be surmised that the alteration effect is less pronounced in the case of carbon isotopes. It seems that the higher δ -values, e.g., those for the sheet-bedded dolomite facies and the large stromatolite facies are least altered and represent near-primary ratios (Veizer *et al* 1992). Higher $\delta^{18}\text{O}$ values in sheet bedded dolomite facies may also be related to dolomitic mineralogy of the samples (Land 1980). As mentioned before, most of the facies constituting the Kajrahat Limestone bears evidence of exposure of the depositional substrate. The $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of small stromatolites and microbial laminites and even cross-stratified dolomites and sheet bedded dolomites probably represent alteration by isotopically lighter fluids at an early stage of diagenesis. Such isotopically lighter fluids can be generated either by organic maturation during burial or organically charged meteoric water (see also Boller and Tucker 2002). Lack of compaction within the Kajrahat Limestone, however, suggests

that diagenetic resetting of carbon and oxygen isotope compositions took place in near surface conditions. Amongst the microbially originated facies of the upper division, microbial laminite facies, as well as both large and small stromatolites, show

emergence features. However, the isotope ratios of large stromatolites are least altered. Scatter in data points and moderate correlation of values in the case of larger stromatolites suggest minor alteration from original values indicating a

Figure 7. $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ plot of the samples of the constituent facies of the Kajrahat Limestone samples displaying wide scatter of data points (a). $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ plot of the Fawn Dolomite samples from three areas, namely Chorhat, Markundi and Dhanjoria (b). $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ plot of the samples of the constituent facies of the Rohtas Limestone samples (c) and Bhandar Limestone (d). Primary box of Ray *et al.* (2003) is indicated by the rectangle in each figure. Note that none of the samples of the Kajrahat Limestone plot within the primary box and all but one sample of the Rohtas Limestone plots outside the primary box.

short duration of exposure in this case (Joachimsky 1994). Microbial laminites, on the contrary, show large depletion of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values suggesting longer duration of exposure. Small stromatolites show moderate depletion of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values in comparison to the large stromatolites. It is possible that the composition of the meteoric fluids varied over time causing the observed scatter in the δ -values. Similar fluctuations in response to shallowing leading to exposure have been documented from many Phanerozoic sequences (Joachimsky 1994). $\delta^{18}\text{O}$ values of the Kajrahat Limestone are highly depleted compared to contemporaneous carbonates and possibly represent considerable diagenetic alteration. As a consequence, none of the values plot within the primary box of Ray *et al.* (2003) although the range of $\delta^{13}\text{C}$ values remains within the 'primary' range (figure 7a). Diagenetic fluids do not contain much CO_2 to reset original carbon isotope signature unless the

alteration effect is extensive and the original carbonate sediments are thoroughly recrystallised. Significant post depositional resetting leading to lowering of $\delta^{18}\text{O}$ values took place possibly for most of the samples of the Kajrahat Limestone.

5.3 Fawn Dolomite

Stable isotope compositions of time equivalent dolomite bodies of the Kheinjua Formation (Fawn Dolomite) vary considerably (table 5). The data points of Chorhat, Markundi and Dhanjoria samples form three separate clusters (figure 7b). The data points of the Fawn Dolomite exhibit good correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values ($r^2 = 0.7$). The Chorhat samples are characterized by consistently negative $\delta^{13}\text{C}$ values ranging from -0.9‰ to -2.8‰ with an average of -1.9‰ . In contrast, the Dhanjoria samples exhibit consistently positive $\delta^{13}\text{C}$ values ranging from 0.9‰ to

1.8‰ the average being 1.4‰. The Markundi samples exhibit $\delta^{13}\text{C}$ values ranging between 0.5‰ to −1.2‰ and are highly depleted in $\delta^{18}\text{O}$. $\delta^{18}\text{O}$ values of the samples steadily become more negative from Dhanjoria (average −6.6‰) to Chorhat (average −8.2‰) to Markundi (average −9.1‰).

The formation of distinct clusters of data points for samples collected from different localities suggests dominant control of paleogeography and local pore fluid on the isotope compositions. As all the samples are mainly dolomitic clustering of points in separate groups it cannot be attributed to mineralogical variation. Diagenetic alteration by meteoric water is equivocal in the inferred depositional setting for the Fawn Dolomite. Meteoric fluids of different compositions might have shifted original carbon and oxygen isotope values towards depleted values. $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of most of

the Dhanjoria samples remain restricted within a narrow range and possibly represent the original carbon and oxygen isotope signature. However, $\delta^{18}\text{O}$ values of the Markundi samples are much depleted and $\delta^{13}\text{C}$ values of the same exhibit a wider range. Modest alteration by isotopically lighter fluids is suggested in the latter case. Good correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values further suggests possible meteoric diagenetic alteration of the dolomites whose original composition was very much similar to the Dhanjoria samples. Petrographic studies show several generations of pore-filling cements within the peloidal dolomites (figures 4c, 4d), corroborating pervasive diagenetic alteration. Ray *et al* (2003) recorded very high Mn/Sr and $^{87}\text{Sr}/^{86}\text{Sr}$ and considered that the samples belonging to the Fawn Dolomite are heavily altered. Paleogeographic setting of the Fawn

Dolomite is the main cause of such an extensive alteration of primary isotope values. As a consequence of such extensive alteration possibly most of the samples of Markundi and Chorhat plot outside the primary box of Ray *et al* (2003); only the samples of Dhanjoria plot inside the primary box.

5.4 Rohtas Limestone

Isotope analyses of 31 samples from all the facies constituting the Rohtas Limestone are given in table 6 and shown in figure 7(c). 20 samples belong to the 10 couplets of the seamed- and non-seamed bands. $\delta^{13}\text{C}$ values of the samples remain restricted in a narrow range from -1.5‰ to -0.3‰ (average

-1‰) whereas $\delta^{18}\text{O}$ values range from -5.2‰ to -8.7‰ (average -6.5‰). $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ cross-plot reveals two broad clusters of data points, one dominated by ribbon limestone facies (seamed part) and the other consists of data points belonging mostly to ribbon limestone facies (but being the non-seamed part). There is a modest correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values ($r^2 = 0.6$). Samples of the calc-arenite facies and thin-bedded limestone facies also plot in the latter cluster. $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ ratios of 10 couplets taken from the seamed and non-seamed bands in ribbon limestone facies reveal a systematic pattern of variation. Every upward transition from seamed lamina to its overlying non-seamed lamina is associated with enrichment in heavy carbon and oxygen isotopes. Within

each couplet, the non-seamed band is enriched in ^{18}O by 0.7‰ to 2.1‰ (average 1.2‰). The same trend is also recorded in ^{13}C (non-seamed band is enriched in ^{13}C , average enrichment being 0.6‰). The shifts are minor in magnitude but significant in their recurrent unidirectional nature and high frequency.

The depositional setting for the Rohtas Limestone was confined to shelf zones. None of the constituent facies represent emergence of the depositional substrate above water level ruling out diagenetic resetting of isotope compositions by meteoric water. The data points of the Rohtas Limestone are, therefore, most likely to retain the original isotope composition. The tight cluster of the data points and the narrow range of $\delta^{13}\text{C}$ values from −1.5‰ to −0.3‰ suggest possible retention of primary isotope signature in most of the samples of Rohtas Limestone. Differential cementation, however, caused marginal shifts in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values within the alternate bands of ribbon limestone facies (Banerjee *et al* 2005). The non-seamed laminae in ribbon limestone facies are always enriched in heavier isotopes of carbon and oxygen than the seamed laminae. The modest correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values can be explained by genetically linked $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ variations of the seamed- and non-seamed laminae. Banerjee *et al* (2005) attributed such repeated shifts in the ribbon limestone facies to pre-compaction differential cementation of the non-seamed bands. Marine cements are always isotopically heavier than the marine sediments; abundance of such

cements within the non-seamed bands can account for the observed enrichment of heavier isotopes in the non-seamed bands (Banerjee *et al* 2005). Most of the data points of the Rohtas Limestones plot within the primary box of Ray *et al* (2003) and thereby corroborate the fact that neither $\delta^{13}\text{C}$ nor $\delta^{18}\text{O}$ values are affected by meteoric diagenesis.

5.5 Bhandar Limestone

In a cross-plot of $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ the data points belonging to the three constituent facies of Bhandar Limestone, e.g., plane laminated mudstone, stromatolites and planar and cross-stratified limestone plot as three separate clusters with very little overlap (table 7, figure 7d). Overall the data points of the Bhandar Limestone exhibit a wide scatter (compare figure 7a–d). Figure 10 shows weak negative correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values ($r^2 = 0.3$). The data points of the stromatolite facies exhibit larger scatter in comparison to those belonging to the planar and cross-stratified facies and plane laminated mudstone facies. The samples from the stromatolite facies exhibit consistently positive $\delta^{13}\text{C}$ values ranging from 0.5‰ to 4.9‰ (average 3‰). The samples of plane laminated mudstone facies also display consistently positive $\delta^{13}\text{C}$ values ranging between 2.9‰ and 4.5‰ (average 3.6‰), whereas the planar and cross-stratified limestone exhibit low negative to low positive values ranging between −1.8‰ and 0.3‰. Average $\delta^{18}\text{O}$ values for stromatolite facies and for plane laminated mudstone facies are −7.7‰ and

–4.3‰, respectively. Planar and cross-stratified facies exhibit intermediate $\delta^{18}\text{O}$ values ranging between –4‰ and –7.4‰ (average –5.1‰).

The occurrence of separate clusters of data points belonging to different facies suggests that the carbon and oxygen isotope compositions are to a large extent controlled by the nature of the facies. Amongst all the carbonate units of the Vindhyan Supergroup the data points of the Bhandar Limestone represent a wide scatter (compare figure 7a to d) and correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of the samples is very poor. Moderate alteration of isotope compositions is thereby suggested for most of the samples of the Bhandar Limestone. Depositional regime for the Bhandar Limestone varied widely extending from distal offshore to shoreface, the planar and cross-stratified facies representing the shallowest bathymetry. Therefore, the observed depletion of $\delta^{13}\text{C}$ in planar and cross-stratified limestone is possibly because of extensive diagenetic alteration due to prolonged exposure in sub-aerial condition. Sarkar *et al* (1998) reported extremely depleted $\delta^{13}\text{C}$ values in meteoric diagenetic cements close to the unconformity surfaces where the $\delta^{18}\text{O}$ values of the same cements were similar to that of the carbonate sediments. It is intriguing that the $\delta^{13}\text{C}$ values are mostly depleted in planar and cross stratified facies without much depletion of $\delta^{18}\text{O}$ values in the same samples. Depleted $\delta^{18}\text{O}$ values of the stromatolite facies are possibly caused by diagenetic resetting by isotopically lighter fluids. Paleogeography of the stromatolite facies varies considerably and allows the carbonates to interact with pore fluids of different compositions. The stromatolite facies thus exhibits maximum scatter of data points out of the three facies. In plane laminated mudstone facies occurrence of enriched $\delta^{18}\text{O}$ values could be due to the dolomitization effect (Land 1980). All the samples belonging to the planar and cross stratified facies plot outside and a few samples from stromatolite facies and plane laminated mudstone facies plot inside the primary box of Ray *et al* (2003). It can be mentioned that meteoric diagenetic alteration of isotope values is already anticipated for the samples of planar and cross stratified facies based on paleogeographic setting and their effect on isotope ratios. Plot of the data points of the planar and cross stratified facies outside the ‘primary box’ further supports the concept of altered isotope signature within the facies.

6. Conclusions

The carbonate facies of the Vindhyan Supergroup represents a wide spectrum of depositional

processes. Supratidal, shoreface, intertidal, shallow subtidal, lagoonal, estuarine, inner and outer shelf carbonates characterise wide variations in facies and paleogeography. Carbon and oxygen isotope compositions of the constituent facies of the different carbonate units frequently form clusters of data points with moderate to negligible overlap. Original carbon and oxygen isotope compositions of many of the carbonate samples are altered because of diagenetic resetting by isotopically lighter fluids. However, carbon and oxygen isotope compositions of the Rohtas Limestone possibly remained unaltered because depositional substrate was not exposed to allow percolation of meteoric fluids through the carbonate sediments. On the contrary, most of the samples of Kajrahat Limestone (intertidal to supratidal origin) represent depleted $\delta^{18}\text{O}$ values possibly because of diagenetic resetting by isotopically lighter fluids. Scatter of the data points in the latter possibly relates to duration of exposure of the depositional substrata. Both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of the other two carbonate units, namely Bhandar Limestone and Fawn Dolostone have been altered considerably because of meteoric diagenetic effect. Besides the depositional setting, mineralogy of the carbonates are also responsible for the observed scatter in the data points and formation of clusters; elevated $\delta^{18}\text{O}$ values have been noticed in a few facies consisting essentially of dolomites. Stable isotope compositions possibly remain close to primary values when early diagenesis takes place in marine setting, e.g., in the case of Rohtas Limestone. Chemostratigraphic significance of carbon and oxygen data is thus reduced in the case of very shallow marine carbonates, which are likely to be flushed by meteoric water. Our interpretations regarding near primary and altered isotope signatures match closely with the inferences drawn by Ray *et al* (2003).
