**e-mail: aivanov@crust.irk.ru*

Siberian Traps Large Igneous Province (STLIP) is one of the most voluminous volcanic provinces on Earth. The dominant erupted rocks are low-Ti basalts, which make up 80% by volume of the classical Noril'sk lava sequence. In the west Siberian basin and Maymecha-Kotuy area, the low-Ti basalts make up about 99% and 50% by volume, respectively. Dolerite sills in the Angara-Taseevskaya Syncline at the southeastern STLIP exhibit trace element patterns and Sr isotope ratios typical of the low-Ti basalts of the Noril'sk sequence. The most Mg-rich (MgO 9.5–11 wt%) and hence least differentiated dolerites are characterized by trace element patterns with Ta-Nb depletion, low Ce/Pb and high Sr/Pr. These trace element features are similar to water-saturated, mantle wedge-derived island arc basalts. These imply an important role of subduction fluid-derived trace elements in the source of melting beneath the Angara-Taseevskaya Syncline and other regions of the STLIP. Less magnesium rocks (MgO 3.8–6.1 wt%) with less prominent Ta-Nb depletion, higher Ce/Pb and lower Sr/Pr could be produced via olivine-plagioclase fractionation of primary high-magnesium melts.

1. Introduction

The Siberian Traps Large Igneous Province (STLIP), covering about $7 \times 10^6 \text{ km}^2$ (figure 1) and with a volume of about $4 \times 10^6 \text{ km}^3$ (Masaitis 1983; extreme estimations of the volume reach $1.6 \times 10^7 \text{ km}^3$, Dobretsov 2005), is one of the largest magmatic provinces on the Earth and probably the largest magmatic province emplaced on the continental lithosphere. The STLIP is of general scientific interest because of the apparent temporal coincidence of the volcanism and Permo-Triassic biotic crisis (Erwin *et al* 2002; Erwin 2003), and is of economic interest because it hosts giant Pt-Cu-Ni, Fe and other types of economically-important deposits (Feoktistov 1978; Zolotukhin *et al* 1986; Ryabov *et al* 2001;

Zolotukhin 1997; Lightfoot and Keays 2005). Interest in STLIP magmatism is reflected in a growing number of publications and continuing debate on the causes of its origin (Zorin and Vladimirov 1989; Renne and Basu 1991; Sharma *et al* 1991; Campbell *et al* 1992; Lightfoot *et al* 1993; Wooden *et al* 1993; Arndt *et al* 1995; Basu *et al* 1995; Fedorenko *et al* 1996; Fedorenko and Czamanske 1997; Walker *et al* 1997; Basu *et al* 1998; King and Anderson 1998; Tanton and Hager 2000; Fedorenko *et al* 2000; Puffer 2001; Ryabchikov *et al* 2001; Jones *et al* 2002; Reichow *et al* 2002; Kamo *et al* 2003; Medvedev *et al* 2003; Al'mukhamedov *et al* 2004; Elkins-Tanton 2005; Ivanov and Balyshev 2005; Ivanov *et al* 2005; Reichow *et al* 2005; Saunders *et al* 2005). Volcanic and intrusive rocks from many localities of

Figure 1. Siberian Traps Large Igneous Province (simplified and modified after Masaitis 1983). Position of the Mongolo-Okhotsk Suture Zone and Permo-Triassic volcano-plutonic complexes of Mongolia and Transbaikalia (Russia) are shown after Zorin (1999) and Yarmolyuk *et al* (2001), respectively. WSB – West Siberian Basin, N – Noril'sk, MK – Maimecha-Kotuy, P – Putorana, TS – Tunguska Syncline, ATS – Angara-Taseevskaya Syncline, KB – Kuznetsk Basin, TB – Transbaikalian Belt.

the vast region of the STLIP have been sampled and analyzed for trace elements and selected isotopes. Among such regions are the classical Noril'sk lava sequence (Sharma *et al* 1991; Lightfoot *et al* 1993; Wooden *et al* 1993; Fedorenko *et al* 1996; Walker *et al* 1997; Al'mukhamedov *et al* 2004), Putorana plateau (Sharma *et al* 1991; Basu *et al* 1998; Ryabchikov *et al* 2001; Al'mukhamedov *et al* 2004), Maymecha-Kotuy area (Arndt *et al* 1995; Basu *et al* 1995; Fedorenko *et al* 1997, 2000; Al'mukhamedov *et al* 2004), Tunguska Syncline (DePaolo and Wasserburg 1979) and the west Siberian basin (Medvedev *et al* 2003; Reichow *et al* 2005) (figure 1). The southeastern part of the STLIP, though sampled in the 1960–70s (e.g., Feoktistov 1961, 1978), remained practically free of geochemical study. In this paper we report inductively coupled plasma mass spectrometry (ICP-MS) data for 25 trace elements and complementary data for Sr isotopes measured in dolerite samples from Tolstomysovskii and Usol'skii sills of the Angara-Taseevskaya Syncline (figure 1). These datasets are compared with the Noril'sk lava

sequence and other parts of the STLIP and then discussed in the light of different models of the STLIP origin.

2. Age of the dolerite sills

The geological setting of the dolerite sills within the Angara-Taseevskaya Syncline were considered in detail by Feoktistov (1978). The term Angara-Taseevskaya Syncline was introduced by Malitch (1999), and refers to an area between the Angara and Taseeva rivers. This is the same as the term Kansk-Taseevskaya Basin coined by Feoktistov (1978) and used in a subsequent publication by Ivanov *et al* (2005). The latter term may not be suitable since it comes from the geographic names of the rivers Kan and Taseeva, which are located far to the west of the sills. Generally speaking, six large dolerite sills (namely, Padunskii, Tolstomysovskii, China-Biryusinskii, Tulunskii, Zayarskii and Usol'skii) have been mapped within the basin on the basis of drilling and field geology.

The sills can be traced for hundreds of kilometers within the basin with varying thickness from 20 to 200 m. The volume of the sills is $6.7 \times 10^4 \text{ km}^3$ (Vasil'ev *et al* 2000), which is relatively small in comparison to the whole STLIP ($> 10^6 \text{ km}^3$).

There are no direct geological relations between the sills with which to establish their relative chronology. However, three upper (by elevation) sills; the Padunskii, Tolstomisovskii and China–Biryusinskii sills are considered to be the oldest (Feoktistov 1978). They are visible in limited surface outcrops and numerous bore-holes in the western and eastern parts of the basin suggest that these sills actually comprise large bodies emplaced mainly within Ordovician and Silurian sediments. In some areas the Padunskii and Tolstomisovskii sills pass through the Ordovician and Silurian sediments and intrude tuffs belonging to the Tutonchanskaya and Korvuchanskaya Early Triassic suites (Domyshev 1974). The Tulunskii sill has been identified mainly in boreholes within the Upper Cambrian to Lower Ordovician sediments. The Zayarskii and Usol'skii sills are recognized as two (probably connected) bodies situated one above the other within the Early Cambrian sediments. Numerous iron-ore-bearing pipes intrude the Early Triassic tuffs and outcropping Padunskii, Tolstomisovskii and China–Biryusinskii sills (Feoktistov 1978). These pipes are probably linked to the Usol'skii sill and therefore the Usol'skii sill was considered to be the youngest (Feoktistov 1978). $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the Usol'skii sill revealed its emplacement in the Early Triassic. Age is $243.9 \pm 1.4 \text{ Ma}$ relative to an age of 129.4 Ma for the LP6 standard or $243.9 \pm 5.8 \text{ Ma}$ if maximal possible inhomogeneity of the LP6 standard is accounted for (Ivanov *et al* 2005). This is significantly younger than the $^{40}\text{Ar}/^{39}\text{Ar}$ age of the Noril'sk-I intrusion calculated relative the same standard. Noril'sk-I intrusion is coeval with the Permo-Triassic boundary (Renne 1995; see Ivanov *et al* 2005 for discussion). More recent $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the Tulunskii, Tolstomisovskii and China–Biryusinskii sills revealed their Middle Triassic ages (Ivanov *et al* submitted). On basis of these two $^{40}\text{Ar}/^{39}\text{Ar}$ studies it is not evident whether Usol'skii and Tolstomisovskii sills represent different magmatic pulses. However, it is evident that the doleritic sills were emplaced within the Angara–Taseevskaya Syncline significantly (6 to 10 Ma) later than the major Permo-Triassic pulse of magmatism of the STLIP (Renne and Basu 1991).

3. Samples and analytical methods

For this study we have chosen 12 whole-rock samples and 8 plagioclase separates from the Usol'skii

and Tolstomysovskii sills. We also include data for four samples from Tulunskii, Tolstomisovskii and China–Biryusinskii sills dated by $^{40}\text{Ar}/^{39}\text{Ar}$ method in a complementary study (Ivanov *et al* submitted) (figure 1). On the basis of variations of major elements these samples can be considered as representative (figure 2a). All plagioclase mineral separates were from the Usol'skii sill. Samples from the Usol'skii sill are from a bore-hole of about 3 km depth. Samples from the Tolstomysovskii sill are from the shallow depth. Samples from the $^{40}\text{Ar}/^{39}\text{Ar}$ study of Ivanov *et al* (submitted) are from surface outcrops and shallow bore-holes. Petrographic descriptions, variations of major elements, and concentrations of a limited number of trace elements and gases in these and other sills were reported previously (Feoktistov 1961, 1978, 2003; Letnikov *et al* 1980).

In sampling site, the Tolstomysovskii sill represents $\sim 250 \text{ m}$ thick body. The lower half of the sill is represented by olivine-rich samples. For example, samples 851, 887, 888 and 891 picked up at depths of 131, 198, 203 and 218 m contain respectively 7.7, 12.8, 14.7 and 17.8 vol.% of olivine (here and further the petrographical data are after Feoktistov 1961 if not stated otherwise). The middle part of the sill is represented by the most differentiated olivine-exhausted samples. Samples 847 (1.1 vol.% of olivine) 833 and 834 (olivine-free) come from this part. The upper (about 25 m) part of the sill again contains olivine-bearing samples (up to 14 vol.% of olivine). Sample 3A (most northern sample from the study of Ivanov *et al* submitted (figure 1)) picked up from the surface outcrop represents this part of the sill. Composition of olivine crystals changes from Fo₇₀ in samples of the lowermost part of the sill to Fo₄₀ in the olivine-exhausted samples of the intermediate part and then to Fo₈₀ in the uppermost samples. The amount of plagioclase and pyroxene crystals varies non-systematically between different samples. Sample 891 is characterized by the highest amount of plagioclase (58.2 vol.%) and lowest amount of pyroxene (20.5 vol.%) among studied samples of the Tolstomysovskii sill. In contrast, sample 834 is characterized by the lowest amount of plagioclase (44.5 vol.%) and highest amount of pyroxene (37.0 vol.%). Other samples exhibit intermediate variations between these two extreme cases. Composition of plagioclase crystals changes from An_{60–65} in the lowermost and uppermost samples towards An₄₀ in the olivine-exhausted samples of the middle part of the sill. Pyroxenes are represented mainly by augite crystals. Pyroxene composition changes from the lowermost towards uppermost samples in the direction of decreasing MgSiO₃ content (from 40–41% to 27%). Besides plagioclase, rare evolved samples (referred to as

granophires) contain K-Na feldspar and quartz crystals. These samples usually show a greater degree of alteration and were thus not included in our study. Recently, dolerite samples with primary magmatic biotite were also found (see thin section image in Ivanov 2007).

Usol'skii sill is generally thinner and is about 200 m thick in the sampling site of the Severo-Markovskaya bore-hole (Feoktistov 1978; Ivanov *et al* 2005). Petrographically Usol'skii sill dolerites are akin to Tolstomysovskii sill dolerites and they reveal similar trends of mineral variations with olivine-exhausted samples in the intermediate part of the sill (Feoktistov 1978). The major difference is in the practical absence of samples with the amount of olivine above 10 vol.%. Samples of the Usol'skii sill are generally more altered compared to fresh samples of the Tolstomysovskii sill. It is worth mentioning, that Usol'skii sill is not so well studied because it is not outcropped on the surface.

Initially, major elements in the Tolstomysovskii and Usol'skii dolerites were measured by classical wet chemistry at the Institute of the Earth's Crust of the Siberian Branch of the Russian Academy of Sciences (IEC SB RAS) and Central Chemical Laboratory of the Irkutsk Office of the Geological Survey (CCL IO GS), respectively (Letnikov *et al* 1980). To verify systematic higher titanium content in published analyses for dolerites of the Usol'skii sill, the available samples were reanalyzed at the IEC SB RAS (analysts Smagunova M.M., Koltunova E.G.). The TiO_2 contents measured at the CCL IO GS were in some cases higher than those measured at IEC SB RAS starting from TiO_2 of 1.9 wt.%. Especially, in one sample (2846) from the Usol'skii sill an anomalously high TiO_2 content of 3.3 wt.% was measured at CCL IO GS (Letnikov *et al* 1980). This sample was not available for additional analytical work, so we do not use this anomalous value in this paper despite the measurement of a $^{87}\text{Sr}/^{86}\text{Sr}$ ratio in plagioclase separates from the same sample.

Whole-rock samples were analyzed for trace elements by ICP-MS. The instrument used is a quadrupole mass-spectrometer PlasmaQuad 2+ of the Baikal analytical center of the Irkutsk Scientific Center of the SB RAS (BAC ISC SB RAS). The operating conditions for the instrument were described by Ivanov *et al* (2000). We used a microwave oven acid dissolution technique for the sample preparation. Details of the analytical procedure were reported previously (Yasnygina *et al* 2003). The accuracy of the measurements was estimated from repeated analyses of BHVO-1 SRM. For all elements it was better than 4.5% (1sd) with exception for Ho, Sm (5–7%) and Tm, Yb,

Pb (8–10%). Measured concentrations of 25 trace elements in the whole-rock dolerite samples are listed in table 1.

For strontium isotope measurements, we used plagioclase separates and whole-rock samples. Plagioclases were selected from large size samples by crushing, sieving, separating on water-flowing table, using heavy liquids and final handpicking. They were dissolved by the same technique as the whole-rock samples. Strontium was separated by means of ion-exchange chromatography using SrSpec resin (Elchrom Industries, USA). We followed the modified procedure of Pin and Bassin (1992) with elution of strontium by pure water (Demonterova and Maslovskaya 2003). Strontium isotopes were measured by conventional thermal ionization mass-spectrometry at BAC ISC SB RAS using a Finnigan MAT 262 mass-spectrometer. Measured isotope ratios were normalized using the Rayleigh law to $^{86}\text{Sr}/^{88}\text{Sr}$ of 0.1194. The long-term repeated measurements of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for SRM NBS 987 was 0.710300 ± 0.000019 (1 sd, $n = 33$). This is the highest value among those reported in literature (Orihasi *et al* 1997). So, we additionally corrected the measured values to be consistent with suggested value of 0.71025 for SRM NBS 987 (Orihasi *et al* 1997). Accuracy of the $^{87}\text{Sr}/^{86}\text{Sr}$ isotope measurements was tested through repeated analyses of AGV-1 SRM. The obtained value after correction to SRM NBS 987 of 0.71025 for AGV-1 was 0.703984 ± 0.000015 (Demonterova and Ivanov 2003) in good agreement with published values (Pin and Bassin 1992; Pin *et al* 1994), when these published values are corrected to the same value of 0.71025 for the SRM NBS 987. Pin and Bassin (1992) and Pin *et al* (1994) reported the lowest value for the SRM NBS 987 (Orihasi *et al* 1997). Rubidium–strontium ratios were determined by isotope dilution by using a mixed Rb–Sr tracer.

Measurements of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio in whole-rock sample 2848 from the Usol'skii sill and a plagioclase separate from the same sample revealed a significant difference (table 2). This difference may reflect secondary alteration of the sample. To remove the effect of the secondary alteration we applied an acid leaching procedure for one additional sample from the Usol'skii sill and for three samples from the Tolstomysovskii sill. The leaching procedure was as follows: Sample powders (200 to 400 mg mass) were treated with 4 ml 6 M HCl in a microwave at 40% output power in 5 cycles of 20 to 30 s each. After these leaching steps and careful removal of the acid, the samples were washed with 6 ml H_2O overnight and then in 3 cycles of 20 to 30 s in the microwave oven, changing the used H_2O each time. After these washing steps and careful removal

of the H₂O, the samples were dried. The leached samples were analyzed for Sr-isotopes as other samples. Isotope ratios were measured at Institute of Precambrian Geology and Geochronology RAS using Finnigan MAT 261 mass-spectrometer.

The leaching procedure decreased both the $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in the sample from the Usol'skii sill, leading to a significant decrease of the initial $(^{87}\text{Sr}/^{86}\text{Sr})_0$ ratio (table 2). The difference between $(^{87}\text{Sr}/^{86}\text{Sr})_0$ ratios in

Note: Average errors for $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ are about 0.8% and 10 ppm, respectively. $(^{87}\text{Sr}/^{86}\text{Sr})_0$ values were calculated for time 244 Ma and 250 Ma for Usol'skii and Tolstomysovskii sills, respectively. Delta TiO_2 is the deviation from the discrimination line on TiO_2 -Mg-number diagram for whole rocks (figure 3b). n.a. – whole-rock sample is not available.

plagioclases from other samples and the leached whole-rock sample 2847 became very small. In samples from the Tolstomysovskii sill, the leaching procedure slightly increased both $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios, leading to a small increase of the $(^{87}\text{Sr}/^{86}\text{Sr})_0$ ratios. Different results of the leaching procedure demonstrate moderate post-intrusion alteration of the Usol'skii sill emplaced deep within the sediments of the Angara-Taseevskaya Syncline and almost no alteration for the shallow Tolstomysovskii sill.

4. Classification of the dolerite samples

According to TAS diagram Tolstomysovskii sill dolerites lie below Macdonald and Katsura (1964) divider line and belong to the tholeiitic rock series (figure 2a). Usol'skii sill dolerites spread along the Macdonald and Katsura (1964) line and are thus transitional between the tholeiitic and alkaline rock series. On ternary AFM diagram, all samples fall into the field of the tholeiitic rock series (not shown). If normative minerals are considered then most magnesium-rich Tolstomysovskii sill dolerites having normative olivine and hypersthene should be classified as olivine tholeiites, whereas the differentiated melts with low MgO (~ 4 wt.%) are silica saturated that is reflected in their normative

quartz mineralogy. So, they should be classified as quartz tholeiites. Three samples of the Usol'skii sill dolerites plotted above the Macdonald and Katsura (1964) line have normative nepheline reflecting their elevated alkalinity (figure 2). Other two samples are characterized by normative olivine and hypersthene. It is long known (e.g., Vilenskii 1967) that Siberian traps, including Angara-Taseevskaya syncline dolerites, have some similarities with calc-alkaline rock series. It is reflected in elevated Al_2O_3 and typical calc-alkaline trends in SiO_2 vs. CaO diagram (figure 2a, b) (see Sheth *et al* 2002 for review of definition of the calc-alkaline series). Further, we do not use the terms tholeiitic and calc-alkaline to describe the Angara-Taseevskaya Syncline sills. Instead we apply the classification scheme developed specially for the Noril'sk lava sequence of the STLIP (Fedorenko *et al* 1996).

The Noril'sk lava sequence is subdivided into a number of lava suites (figure 3a) on the basis of lithology and petrography (e.g., Zolotukhin *et al* 1986). It has been shown that these suites are also distinct in major and trace elements (Lightfoot *et al* 1993; Wooden *et al* 1993; Fedorenko *et al* 1996; Al'mukhamedov *et al* 2004). Suites can also be grouped into two or three major chemostratigraphic sequences. The lower stratigraphic sequence includes three suites, which are represented by basalts, trachybasalts and rare

Figure 2. Total alkalis and CaO *vs.* silica classification diagrams. Analyses are recalculated on a water-free basis. Solid discriminating lines are from Le Bas and Streckeisen (1991). Dashed discriminating line marked MK is from Macdonald and Katsura (1964). Fields in figure 2(a) mark chemical variations of the sills according to Letnikov *et al* (1980). Symbols represent samples used in this work. Samples from study of Ivanov *et al* (submitted) were analyzed at IEC SB RAS like other samples. Sample 3A is from Tolstomysovskii sill. Solid lines traced through the data points in figures 2(a) and 2(b) are linear regressions.

basaltic andesites with generally high TiO_2 content (figure 3a, b). These compositions make up only about 20% of the total volume of the lava sequence in the Noril'sk area. The remaining 80% is composed of low-Ti basalts and picrobasalts. The uppermost part of the lava sequence also contains high-Ti trachybasalts, ankaramites and moderately enriched in Ti basaltic andesites, which are volumetrically negligible and not considered here. Lightfoot *et al* (1993) have shown that high-Ti and low-Ti basalts can be distinguished on a TiO_2 –Mg-number diagram. Ivanov and Balyshev (2005) suggested using a delta TiO_2 notation, where delta TiO_2 is the deviation from the discrimination line on TiO_2 –Mg-number diagram for whole rocks (figure 3b, c). Fedorenko *et al* (1996) have shown that high-Ti and low-Ti rocks at Noril'sk can also be separated on the basis of their Gd/Yb ratio. High-Ti rocks are also high in Gd/Yb, whereas the low-Ti rocks are low in Gd/Yb (figure 3d). Further subdivision of the low-Ti rocks is possible based

Figure 3. Classification of the Usol'skii and Tolstomysovskii sill dolerites on the basis of their comparison with the Noril'sk lava sequence. (a) Stratigraphic position of the lava suites within the Noril'sk area (suites: iv – Ivakinsky; sv – Syverminsky; gd – Gudchikhinsky; hk – Hakanchansky; tk – Tuklonsky; nd – Nadezhdinsky; mr – Morongovsky; mk – Mokulaevsky; hr – Haraelakhsky; km – Kumginsky; sm – Samoedsky). Tran. is an acronym for transitional series between low-Ti-1 and low-Ti-2. It belongs to middle sequence according to Fedorenko *et al* (1996). (b) Classification by titanium content and Mg-number = $[\text{Mg}/(\text{Mg} + 0.85\text{Fe}_{\text{total}})]$, where elements are presented in atomic units and Fe_{total} calculated from $\text{FeO}_{\text{total}}$. Originally suggested by Lightfoot *et al* (1993). Subdivisions to high- and low-Ti series after Ivanov and Balyshev (2005). (c) Variations in $(^{87}\text{Sr}/^{86}\text{Sr})_0$ relative to the titanium series. Delta TiO_2 is deviation from the discrimination line calculated as $\text{TiO}_2 = 3.45 - 0.0317 \times \text{Mg-number}$. (d) Classification by Th/U and Gd/Yb ratios as suggested by Fedorenko *et al* (1996). Geochemical and Sr-isotope data for Noril'sk are after Lightfoot *et al* (1993); Wooden *et al* (1993); Al'mukhamedov *et al* (2004) and Fedorenko *et al* (1996). Original data are plotted as symbols (the same as in figure 2). Th and U (as well as other trace elements shown in subsequent figures) in the samples from the study of Ivanov *et al* (submitted) were analyzed at Institute of Geology and Geophysics SB RAS, Novosibirsk, Russia by ICP-MS technique described in Shatsky *et al* (2006). In (c) triangles connected by lines represent leached and unleached sample and plagioclase and whole-rock sample.

Figure 4. Chondrite- and primitive mantle-normalized diagrams for dolerites of Tolstomysovskii and Usol'skii sills. Average compositions of the low-Ti-1 group and low-Ti-2 group basalts from Noril'sk lava sequence are shown for comparison (data for calculating averages are after Lightfoot *et al* 1993; Wooden *et al* 1993 and Al'mukhamedov *et al* 2004). Symbols for the suites are as in figure 3. Compositions of the chondrite and primitive mantle are after McDonough and Sun (1995).

on their Th/U ratios. Lavas from the middle and upper sequences are lower (low-Ti-1 group) and higher (low-Ti-2 group) in Th/U ratio, respectively (figure 3a, d). Three chemostratigraphic sequences are also distinct in Sr-Nd-Pb isotopes (Lightfoot *et al* 1993; Wooden *et al* 1993; Fedorenko *et al* 1996; Al'mukhamedov *et al* 2004). Lavas of these sequences are not related to each other by differentiation processes and probably have been derived from two (Ivanov and Balyshev 2005) or more (Fedorenko *et al* 1996) distinct sources of magma within mantle and/or continental crust.

We apply the same chemostratigraphic principles to classify dolerites of the Angara-Taseevskaya Syncline. Tolstomysovskii sill dolerites approach a field of the low-Ti-2 group of the middle lava sequence of the Noril'sk, whereas Usol'skii sill dolerites resemble low-Ti-1 group of the upper lava sequence of the Noril'sk on all classification diagrams (figure 3b, c, d). However, leaching procedures shifted samples of the Usol'skii sill with near zero δTiO_2 values towards lower $(^{87}\text{Sr}/^{86}\text{Sr})_0$

(figure 3c). It is worth mentioning that the Noril'sk samples were not leached and the increase of δTiO_2 values with the increase of $(^{87}\text{Sr}/^{86}\text{Sr})_0$ in basalts of the upper sequence at Noril'sk may reflect secondary alteration, as documented for the Usol'skii sill dolerites. The lower Th/U in Tolstomysovskii sill dolerites in comparison to higher Th/U in basalts of the middle sequence at Noril'sk can be in part due to slight analytical bias between Fedorenko *et al* (1996) and this study. Dolerite samples from Tulunskii, Tolstomysovskii and China-Biryusinskii sills (Ivanov *et al* submitted) belong to the low-Ti-1 group. It is worth mentioning that these samples were selected to satisfy selection criteria for $^{40}\text{Ar}/^{39}\text{Ar}$ dating rather than to characterize the compositional range of different sills. However, it is obvious that low-Ti-1 group type of magma is dominant within the Angara-Taseevskaya Syncline.

Geochemical similarities between the Angara-Taseevskaya sills and the low-Ti Noril'sk lavas are clearly seen on multielement diagrams. Magnesium-rich dolerites of the Tolstomysovskii

sill closely follow REE and other trace element patterns of an average composition of the basalts from the Tuklonsky suite (low-Ti-2 group) with exceptions for U, Nb, Pb, and P (figure 4a, b). Usol'skii sill dolerites are similar to REE and other trace element patterns of an average composition of the basalts from the low-Ti-1 group (Morongovsky-2 to Samoedsky suites) with exception for Rb, P and also K, Nb and Ta (figure 4c, d). Low-magnesium dolerites of the Tolstomysovskii sill are similar to the dolerites of the Usol'skii sill. Nb peaks on the multi-element mantle normalized diagrams for averages of the Noril'sk lava suites may be an analytical artifact because data of Wooden *et al* (1993) show unrealistically high Nb/Ta compared to data of Lightfoot *et al* (1993) for the same lava suites. Samples from Tulunskii, Tolstomysovskii and China-Biryusinskii sills of Ivanov *et al* (submitted) fall into a narrow range of compositions, which is similar to a range of low-Mg samples of the Tolstomysovskii sill.

Summarizing the comparison between dolerites of the Angara-Taseevskaya Syncline and basalts of the Noril'sk lava sequence, we note that they exhibit rather more similarities than differences. High-magnesium dolerites (Tolstomysovskii sill) and low-magnesium dolerites (Usol'skii sill and Tolstomysovskii sill) can be considered as geochemical analogues of the low-Ti-2 and low-Ti-1 groups of the Noril'sk area, respectively. However, the Usol'skii and Tolstomysovskii sills are 6 to 10 Ma younger than the lava sequence at Noril'sk (Ivanov *et al* 2005; submitted). In other words, in both areas similar processes were responsible for origin of the low-Ti magmas, but these processes acted during different pulses of volcanism.

5. Crystal fractionation and parental low-Ti melts

Low-Ti-1 group of dolerites are too low in magnesium to be considered primary melts. Crystal fractionation as a cause of major element variations for the Angara-Taseevskaya dolerite sills have been considered previously by Feoktistov (1961, 1978). He noted the following order of mineral crystallization; ol + mt or ol + pl + mt; ol + pl or ol + pl + aug; pl + aug or aug; pyrrh (where ol – olivine, pl – plagioclase, aug – augite, mt – magnetite, pyrrh – pyrrhotite). Similar mineral crystallization assemblages have been reported for Noril'sk region (e.g., Fedorenko *et al* 1996) and west Siberian basin (Reichow *et al* 2005).

Low-Ti dolerites have prominent signatures such as enrichment of Pb and Sr relative Ce and Pr (figure 4). To check if any of these signatures are dependent on mineral crystallization we focus on

Figure 5. Mg-number, normative An and CaO/Al₂O₃ vs. Sr/Pr for dolerites of the Tolstomysovskii and Usol'skii sills. Symbols are as in figure 2.

the effect of olivine, plagioclase and augite fractionation. Fractionation of magnetite and other ore minerals in most instances are volumetrically insignificant and is thus not considered here.

Mineral/melt partition coefficients of Sr and Pr for most basaltic minerals are below 1 and also similar to each other (e.g., Sun and McDonough 1989; Hart and Dun 1993), but plagioclase/melt partition coefficient of Sr is above unity (e.g., Dun and Sen 1994). Therefore only plagioclase fractionation will affect Sr/Pr ratio. Plagioclase in its turn is almost free of Fe and Mg, and hence its fractionation does not affect Mg-number. Therefore, perfect correlation in Mg-number vs. Sr/Pr diagram for Tolstomysovskii sill dolerites is due to the combined effect of olivine and plagioclase fractionation (figure 5a). Plagioclase composition was changing towards decrease of the anorthite component in the

course of fractionation (figure 5b). Augite fractionation can be tested by $\text{CaO}/\text{Al}_2\text{O}_3$. It can be seen that Usol'skii sill and Tolstomysovskii sill dolerites show two weak opposite trends in $\text{CaO}/\text{Al}_2\text{O}_3$ vs. Sr/Pr diagram (figure 5c).

Plagioclase fractionation will affect not only Sr/Pr but also the ratios of Eu to neighbouring REE (Eu^*/Eu , which is calculated as $\text{Eu}_N/(\text{Sm}_N \times \text{Gd}_N)^{1/2}$, where subscript N is for chondrite normalized values) and Ce/Pb ratios. Plagioclase/melt partition coefficients for Sr and Eu are dependent on the plagioclase composition, which is a function of temperature (Blundy and Wood 1991), and on oxygen fugacity (Irving 1978), respectively. To fit observed variations on Eu^*/Eu vs. Sr/Pr diagrams by a model curve of equilibrium crystallization of plagioclase we used variable partition coefficients (figure 6a). Slight increase of Ce/Pb with decrease of Sr/Pr can also be explained by plagioclase fractionation (figure 6b).

Figures 5 and 6 show that major and trace element features of the low-Ti-1 group low magnesium dolerites can be explained by fractionation of (mainly) olivine and plagioclase from a parental melt with geochemical features similar to the low-Ti-2 group dolerites (e.g., low Ce/Pb of about 5, high Sr/Pr of similar or above 100). However, despite similar geochemical features the primary melts of the low-Ti-1 and low-Ti-2 groups differ in initial $^{87}\text{Sr}/^{86}\text{Sr}$. The former and the latter are characterized by $^{87}\text{Sr}/^{86}\text{Sr}$ of < 0.70465 and about 0.7061, respectively. Some geochemical differences also exist such as different Th/U ratios (e.g., figure 3d) and different trends in Nb/Y-Zr/Y diagram (not shown), which cannot be explained by plagioclase or olivine fractionation.

On the basis of consideration that olivine-rich dolerites are cumulative in origin, Feoktistov (1978) estimated primary melt of the Tolstomysovskii sill to have Mg-number of 56.6, normative An of 56.5 and $\text{CaO}/\text{Al}_2\text{O}_3$ of 0.70. At these values the primary melt of the Tolstomysovskii sill will have Sr/Pr of ~ 100 . Samples 847 and 851 are close to such compositions (table 1, TSPM in figure 6b).

Low-Ti dolerites have also depletion in Nb and Ta relative K (figure 4). We rule out rutile fractionation at depth (or residual rutile in the source of melting) as a cause of this Nb and Ta depletion, because of the following reasoning. Th behaves as incompatible element in rutile, whereas U shows compatible or slightly incompatible behavior (Klemme *et al* 2005). Thus, rutile fractionation will create relative enrichment of Th. The opposite is observed in figure 4.

To summarize, enrichment of Pb relative Ce and Sr relative Pr and depletion of Nb relative K is a characteristic of primary low-Ti magmas.

Figure 6. (a) Eu^*/Eu and (b) Ce/Pb vs. Sr/Pr for dolerites of the Tolstomysovskii and Usol'skii sills. Various mantle and crustal reference components are shown as large open rhombs in (b). PAAS is the average of post Archean Australian shale (Taylor and McLennan 1985; average 1). OIB and MORB are the averages of basalts from within plate oceanic islands and mid-ocean ridges, respectively (Sun and McDonough 1989). BHVO-1 is Hawaiian basalt delivered by USGS as trace element standard. The plotted Ce/Pb of ~ 15 and Sr/Pr of ~ 70 for BHVO-1 are typical values obtained in our (e.g., Barry *et al* 2007; this study) and other laboratories (e.g., Dulski 2001). LCC is an average of the lower continental crust (Rudnick and Fountain 1995). TSPM is a primary melt of the Tolstomysovskii sill based on consideration of cumulative origin of the high-Mg dolerites (Feoktistov 1978). Small open rhombs are high magnesium basalts from Klyuchevskoi volcano, Kamchatka, Russia (Dorendorf *et al* 2000). Other symbols are as in figure 2. Bold curve shows change of the ratios due to plagioclase fractionation. Numbers close to the ticks represent per cent of fractionated plagioclase. The model is calculated according to Shaw (1970) equation for equilibrium crystallization. Plagioclase/melt partition coefficients (D) for Ce, Pr, Sm, Gd and Pb are taken to be constant as 0.1, 0.08, 0.05, 0.04 and 0.73, respectively (the values within published ranges of Dun and Sen 1994). D for Sr and Eu are taken to be variable as function of plagioclase composition and oxygen fugacity. Their values are shown in the figure. The choice of particular D values for Sr and Eu was made to keep their monotonous change with change of Sr/Pr and remain within likely D - $f\text{O}_2$ - T limits (Blundy and Wood 1991; Irvin 1978).

6. Models of origin of primary low-Ti magmas

Several models of the STLIP origin have been discussed in literature. These are “extra-terrestrial”

model of bolide impact (Jones *et al* 2002) and “terrestrial” models of

- (1) plume – lithosphere interaction (e.g., Campbell *et al* 1992; Lightfoot *et al* 1993; Wooden *et al* 1993; Ryabchikov *et al* 2001; Reichow *et al* 2005),
- (2) craton-induced convection (King and Anderson 1998; Puffer 2001),
- (3) lithospheric delamination in concert with a weaker plume (Elkins-Tanton 2005) and
- (4) upper-mantle water saturation due to prolonged subduction (Ivanov and Balyshev 2005).

Here we discuss geochemistry of the Angara-Taseevskaya dolerites, referencing the different terrestrial models. We rule out the extraterrestrial model, induced by temporal coincidence of the voluminous phase of eruptions of the STLIP and Permo-Triassic biotic crisis, because the STLIP magmatism was initiated before the Permo-Triassic boundary and lasted for at least 22–26 million years (Ivanov *et al* 2005) and because there is no obvious world-wide impact signature at that time (Koeberl *et al* 2002). Evaluation of terrestrial models with reference to various observations has been done by Ivanov (2007). Here we focus on particular aspects related to the major topic of the present paper, which is geochemistry of dolerite sills from the Angara-Taseevskaya Syncline.

In section 4, it was shown that the Angara-Taseevskaya dolerites are geochemically similar to low-Ti basalts of the Noril’sk sequence. The low-Ti basalts are also abundant in the west Siberian basin and Maimecha-Kotui area. In the west Siberian basin all published analyses but one belongs to the low-Ti basalts (Medvedev *et al* 2003; Reichow *et al* 2005), and in the Maimecha-Kotui Area the low-Ti basalts make up to 50% by volume (Fedorenko and Czamanske 1997). Therefore, the Kansk-Taseevskaya dolerites may bear general information on the origin of the dominant magma type of the STLIP.

The low-Ti-2 rocks bear prominent geochemical signatures on mantle-normalized diagrams, such as depletion in Ta and Nb, and enrichment in Pb and Sr (figure 4b). These geochemical signatures, which are typical attributes of the lower continental crust (LCC) (Rudnick and Fountain 1995) and island arc basalts (IAB) (Puffer 2001), are also observed to a lesser extent in the low-Ti-1 rocks (figure 4d). In section 4, we have also shown that primary melt of the low-Ti-1 rocks could be similar to low-Ti-2 rocks.

The similarity between the LCC and IAB is not a surprise because a significant portion of the LCC is formed due to basalt underplating in active

Figure 7. Comparison of the low-Ti-1 and low-Ti-2 series with the mantle-derived basalts and crustal reference lines on primitive mantle normalized diagram. IAB is average of high Mg-number basalts of the Klyuchevskoi volcano (Dorendorf *et al* 2000). OIB and MORB are averages of basalts from within plate oceanic islands and middle oceanic ridges respectively (Sun and McDonough 1989). LCC is an average of the lower continental crust (Rudnick and Fountain 1995).

continental margins (i.e., island- and continental volcanic arcs). We plot representative samples of the low-Ti-1 and low-Ti-2 samples on a mantle-normalized diagram together with average compositions of the ocean island basalts (OIB), IAB, normal mid-oceanic ridge basalts (N-MORB) and LCC (figure 7a, b). It may be seen that low-Ti-1 and low-Ti-2 rocks closely follow trace element patterns of the LCC and IAB, whereas they are remarkably different from OIB and N-MORB.

6.1 Plume – lithosphere interaction

It has been suggested that low-Ti-2 group basalts in the Noril’sk area originated from primary plume melts contaminated by crustal material (e.g., Wooden *et al* 1993; Ryabchikov *et al* 2001).

However, we think that *in situ* involvement of the lower crust in the plume model is an unlikely process for explanation of the low-Ti-2 group magma composition for several reasons. First of all, magmas with such compositions were found everywhere within the STLIP, even in regions where no high-Ti magmas, which are believed to represent the plume melts (e.g., Lightfoot *et al* 1993; Wooden *et al* 1993; Reichow *et al* 2005), were recorded (e.g., most regions of the west Siberian basin and Angara-Taseevskaya Syncline). Second and perhaps most importantly, low-Ti-2 group basalts (and dolerites) and high-Ti basalts do not form continuous mixing trends on trace element and isotope diagrams (Fedorenko *et al* 1996; Ivanov and Balyshev 2005; Ivanov 2007). For example on Ce/Pb–Sr/Pr diagram, low-Ti-1 and low-Ti-2 dolerites do not plot between OIB and LCC (figure 6b). Indeed, the low-Ti-2 group is too low in all trace elements to be produced as a mixture between OIB and LCC (figure 7a). OIB shown in figure 6(b) is a modeled composition (Sun and McDonough 1989). However, the conclusion about absence of mixture with LCC remains valid if we take, for example, real Hawaiian basalt (BHVO-1) as a representative of plume melt (figure 6b).

Lightfoot *et al* (1993) modeled some key trace element ratios in low-Ti-2 dolerites as a result of melting of MORB source with added subducted sediments (composition of the MORB varied from normal to enriched types and amount of the sediments – PAAS (Post Archean Australian Shale) varied from 60 to 1% in different models). Low-Ti-1 dolerites are shifted towards this hypothetical mixture (figure 6b). However, low-Ti-1 dolerites of the Usol'skii sill have less radiogenic $^{87}\text{Sr}/^{86}\text{Sr}$ compared to low-Ti-2 dolerites of the Tolstomysovskii sill (table 2). The opposite should be observed. Indeed it is impossible to find a suitable contaminant to explain all trace elements and $^{87}\text{Sr}/^{86}\text{Sr}$ isotopes in high-Mg dolerites. For example, if we take sample 887 from the Tolstomysovskii sill and assume that it represents binary mixture of a hypothetical plume with N-MORB trace element and isotope composition (a common assumption for Siberian Traps) and a hypothetical crustal contaminant (Rudnick and Fountain 1995) with $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.712, then the amount of contaminant is limited to about 10%. From this assumption it is possible to estimate trace element composition of the crustal contaminant. It is easy to see that those elements, which are higher in the sample 887 than in N-MORB (Rb, Ba, Th, U, K, La, Ce, Pb, Sr), should be also higher in the contaminant (70–100 times of primitive mantle normalized values for Rb, Ba, U, K, Pb and 10–50 times for Th, Sr, La and Ce). However, those elements, which are lower in the sample 887 than in N-MORB (Zr, Hf, Sm,

Ti, Y, Yb) should be lower in the contaminant than in the N-MORB (figure 7a). Simple mass balance calculations show that even zero concentrations of these particular elements cannot satisfy our highly conservative estimation of 10% of contaminant based on strontium isotopes. Correction for accumulation of any minerals (for example if we assume that the high MgO in the sample 887 is due to olivine accumulation) cannot change the sense of the above estimations; all heavy REE in the resulted low-Ti melt remain below N-MORB values and these elements will thus approach zero concentrations in the modeled contaminant composition.

Surprisingly also, there is no or very limited place for OIB type melt in any mixing models for origin of the low-Ti melts (OIB-like features are typical only for the lowermost samples of the Ivakinsky suite at Noril'sk (e.g., Wooden *et al* 1993)). We should either accept that the suggested plume had trace element features of LCC or IAB (i.e., high Sr/Pr, low Ce/Pb), or reject the plume as a major source for the STLIP. This feature is not unique for the STLIP and was observed for other continental LIPs situated in back-arc tectonic setting (e.g., Ferrar (Molzahn *et al* 1996)).

6.2 Basic crust recycling

Pushkarev (1997) suggested that the origin of giant Cu-Ni-PGE deposits in the Noril'sk region requires crust-mantle interaction at mantle depth. According to this author the crust and mantle are necessary for sources of elements and heat, respectively. In other words, the model of Pushkarev (1997) is an intuitive model, which is similar to numerical calculation of Elkins-Tanton (2005) for lithospheric delamination. At least some of the eclogites found as xenoliths in Siberian kimberlites bear signatures of their origin in subduction processes (Spetsius 2004), and hence delamination and melting of such eclogites may result in subduction-like signatures of the STLIP magmas. The model of delamination of the LCC is a currently popular alternative to the plume model (e.g., Lustrino 2005).

To explain the geochemistry of low-Ti-2 dolerites of the Angara-Taseevskaya Syncline and basalts of the same geochemical type in other regions of the STLIP in the delamination model, we should accept ultra high degrees of melting ($\geq 50\%$) of the delaminated lower crust at mantle depths, to produce basaltic melts from essentially basaltic sources. Perhaps, such a high degree of LCC contribution is not impossible. For example, up to 50% of the LCC contribution is required to produce Indian Ocean MORB with DUPAL lead isotope signatures and the most radiogenic $^{187}\text{Os}/^{186}\text{Os}$ (Escrige *et al* 2004). Therefore, the LCC delamination model is

generally consistent with geochemistry of the low-Ti type of magma. However, the question is how the lithosphere could be delaminated almost simultaneously on a scale of thousands of kilometers (i.e., the size of the STLIP; figure 1).

Sobolev *et al* (2007) suggest a model in which recycled basic crust (eclogite) within a plume melted and reacted with peridotitic mantle, producing pyroxenitic source for the STLIP. It should be noted that this model for the STLIP is based on analyses of olivines from a part of Gudchihinsky suite at Noril'sk. The Gudchihinsky suite belongs to the high-Ti series, whereas volumetrically dominated rocks (sills of the Angara-Taseevskaya Syncline are no exception) belong to the low-Ti series (figure 3). Though attractive, the model of Sobolev *et al* (2007) cannot be directly applied to the whole STLIP without additional analyses of olivines from rocks of the low-Ti series.

6.3 Melting of water saturated mantle-wedge-like lithospheric mantle

Puffer (2001) pointed out the geochemical similarity between STLIP basalts and island-arc basalts. The similarity reflects their mantle source, which is similar to the mantle-wedge of active continental margins. Initially depleted mantle-wedge is spiked by Rb, Ba, Pb, K, U, Th, Sr and in lesser extent by light REE via water-rich fluid derived from subducting slab, whereas Ta, Nb, Zr, Hf, Ti and heavy REE are not transported by the fluid (e.g., Ulmer 2001). This process makes mantle-wedge and partial melts of the wedge identifiable in terms of trace element patterns observed on mantle-normalized diagrams (e.g., figures 4 and 7). Importantly, after stopping active subduction and cessation of island-arc volcanism some amount of water should remain in the mantle in the form of water-bearing minerals (e.g., amphibole and mica). According to Puffer (2001), such a mantle-wedge source was formed long before the Permo-Triassic magmatism because of paleosubductions beneath the Siberian craton. Shortly before the initiation of Permo-Triassic magmatism, the mantle-wedge source was a part of the continental lithospheric mantle. The fusible water-rich mineral assemblage was melted, producing voluminous but brief volcanism, because of a redistribution of heat in the upper mantle due to craton-induced convection (King and Anderson 1995). As seen from the wide distribution of the low-Ti-2 type basalts in the STLIP, this idea requires an *ad hoc* assumption that lithospheric mantle is essentially the same over a distance of thousands of kilometers (i.e., the scale of STLIP; figure 1).

IAB-like trace element pattern in continental basalts is conventionally considered as a sign

of lithospheric contamination of a plume melt (e.g., Lightfoot *et al* 1993; Reichow *et al* 2005 among many others). Contrary to the conventional view, Kieffer *et al* (2004) analyzed low-Ti and high-Ti basalts from Eocene Ethiopian Traps and concluded that their origin was in sublithospheric mantle. Reviewing various contrary arguments for lithospheric contamination given in literature, Kieffer *et al* (2004) pose a question '*is the label 'lithosphere' just given to the source of any magma whose composition is thought to be inconsistent with that of an asthenosphere or plume source?*'. We see no evidence of mixing between expected plume melt and lithospheric contaminant for the Angara-Taseevskaya dolerites (e.g., figures 6 and 7) and low-Ti melts from other parts of the STLIP (Ivanov 2007) and, therefore, concur with Kieffer *et al* (2004) that low-Ti melts were originated in sublithospheric mantle.

6.4 Melting of water saturated mantle-wedge-like sublithospheric mantle

Keeping the same geochemical argument as Puffer (2001), Ivanov and Balyshev (2005) argued that the water-rich wedge-like mantle was formed shortly before the Permo-Triassic magmatism. In the Permian, Siberia was a part of the Pangean supercontinent, surrounded by subducting slabs (e.g., Nikishin *et al* 2002). The Mongol-Okhotsk Suture Zone (MOSZ), which is the present-day position of the Permian subduction system (e.g., Zonenshain *et al* 1990; Zorin 1999), is about 800 km south of the southeastern end of the STLIP (figure 1). Noril'sk is about 2500 km from the MOSZ. It should be noted that according to paleotectonic reconstructions of the east (in present-day coordinates) there should be another Permian subduction system (Nikishin *et al* 2002).

A Permian-Triassic volcano-plutonic belt was located between MOSZ and Siberian traps (figure 1). This belt is composed of granitic and syenitic batholiths, basaltic and rhyolitic volcanic deposits and dikes. It is poorly characterized by radioisotopic dating (e.g., Yarmolyuk *et al* 2001), but its Permian – Triassic age is generally accepted (e.g., Nikishin *et al* 2002; Dobretsov 2005). There are three principle interpretations of the volcano-plutonic belt;

- (1) the belt is an Andean-type orogen related to subduction (Zorin *et al* 1998; Zorin 1999),
- (2) the belt is an anorogenic phenomenon related to the Siberian mantle plume (Dobretsov 2003, 2005) or
- (3) the belt is related to an independent mantle plume (Yarmolyuk *et al* 2001).

Figure 8. Saturation of the transitional zone with water via subduction and possible regions of melting of water saturated advected mantle peridotite (updated after Ivanov 2007). Figure on the left shows that fast subducting slab attains positive buoyancy while crossing 410 km discontinuity. Both fast and slow subducting slabs attain positive buoyancy while crossing 660 km discontinuity (after Bina *et al* 2001). Figure on the right shows stability fields (shaded) of water-bearing minerals in $\text{CaO} - \text{MgO} - \text{Al}_2\text{O}_3 - \text{SiO}_2 - \text{H}_2\text{O}$ (CMAS + H_2O) system (after Litasov and Ohtani 2003). Water-bearing minerals: Wd – wadsleyite, Rw – ringwoodite, E – dense hydrous magnesian silicate, B and G/D/F – superhydrous phases. Straight lines show boundaries between different mineral assemblages (not included for the sake of simplicity). Curved dotted line shows limits of clinopyroxene stability field (cpx in and out). The symbol ‘Ol’ is located in region of highest solubility (up to 0.9 wt.%) of H_2O by olivine (Smyth *et al* 2006). H_2O solubility of olivine decreases with increasing temperature (Smyth *et al* 2006). White ellipses mark possible depths of melting of water saturated mantle peridotite advected from transition zone. These regions are placed near or just above solidus line in CMAS + 2 wt.% H_2O system marked by hatch-dotted line (Litasov and Ohtani 2003). The regions of melting correspond well by depths with those suggested by Hirschman *et al* (2005). At intermediate depth between the two regions of melting in the upper mantle is characterized by highest water capacity that prevents melting (Hirschman *et al* 2005).

The second interpretation is based on the reasoning that all Permo-Triassic events in the STLIP vicinity are the result of the Siberian plume. The third interpretation is based on the assumption that large belts of alkaline-granites are plume-related. We accept the first interpretation, which accounts for regional geology and geophysics, and plate tectonic paradigm, which holds that subduction beneath a continent is expressed with continental volcanic belts.

The subducting slab can bring a significant amount of fluid into the transition zone of the mantle (mantle between ~ 410 and 650 km discontinuities) far beneath the continent, which decreases

the melting point of the mantle in the transition zone. Figure 8 shows that transition zone can be enriched by water through subduction. Because of a metastable mineral assemblage a rapidly subducting slab attains positive buoyancy while crossing the 410 km discontinuity, and hence should deflect to the horizontal; the same effect is visible for a slowly subducting slab crossing the 660 km discontinuity (Bina *et al* 2001). Superhydrous mineral phases are stable at about these two discontinuities (Litasov and Ohtani 2003).

Consider the top of transition zone (say 450 km depth). Within cold temperature conditions of fast subducting slab, the slab at such depth will keep water within phase E, wadsleyite and, probably, clinopyroxene (figure 8b). The phase E and wadsleyite contains about 11 wt.% and up to 3 wt.% of H_2O , respectively (Litasov and Ohtani 2003; Ohtani 2005). Assuming that D between clinopyroxene and orthopyroxene is equal to 1, the clinopyroxene at depths of 450 km may contain up to 2 wt.% of H_2O (Hirschmann *et al* 2005). With warming the slab up to temperature of the ambient mantle, the water content in the slab will decrease due to, first, decomposition of the phase E, second, decrease of water content in wadsleyite (figure 8b). The released water could be accommodated by clinopyroxene, but clinopyroxene becomes practically absent while the slab is warmed up to temperature of normal mantle geotherm (figure 8b). Therefore, if slab is not completely degassed during subduction the remained water will be released after the slab stagnation in the transition zone as free fluid phase (figure 9).

Addition of water into transition zone via subduction is expected to create partial melts (Bercovici and Karato 2003; Huang *et al* 2005). Silicate melt in the transition zone is lighter than ambient mantle and should rise due to its own buoyancy. In the lowermost part of the upper mantle, the silicate melt is denser than the ambient mantle and hence it should be trapped as a melt layer (Bercovici and Karato 2003; Matsukage *et al* 2005; Sakamaki *et al* 2006). Hirschmann *et al* (2005) estimated water capacity of the lowermost upper mantle between 0.4 and 1.2 wt.% with preferred value of 0.5 wt.%. Therefore, melt at the bottom of the upper mantle should have an amount of water in excess of the upper mantle water capacity. The question either melt layer may exist, does it exist locally or globally and can it rise to the surface is debatable (Bercovici and Karato 2003; Hirschmann *et al* 2005; Huang *et al* 2005; Matsukage *et al* 2005; Sakamaki *et al* 2006). According to recent experiments, at about 410 km depth the silicate melt will rise due to its own buoyancy with water saturation up to about 6 wt.% (Matsukage *et al* 2005; Sakamaki *et al*

Figure 9. Schematic representation of LIP magmatism in connection with water saturation of the transition zone via subduction processes. Transition zone is thicker than average in both cold and wet regions (e.g., Bina and Helffrich 1994; Litasov *et al* 2005). Numbers represent key steps: ① – subduction of water-rich oceanic crust and its incomplete dewatering beneath volcanic arcs; ② – carriage of water with nominally anhydrous minerals by subducting slab; ③ – storage of water by water-bearing minerals within stagnating slab; ④ – release of water due to warming of the stagnating slab up to the ambient mantle temperature (partial melting probably occurs within recycled oceanic crust and/or transition zone mantle); ⑤ – carriage of water with wet peridotite diapirs; ⑥ – relatively long-term supersolidus conditions beneath thick lithosphere (voluminous melting of peridotite upper mantle); ⑦ – drainage event probably due to tectonic causes. Steps 6 and 7 are concurring with Silver *et al* (2006). LIP and arc magmatism are similar in geochemical point of view because water carries preferentially large ion lithophile elements (e.g., Ba, K, Sr), but do not carry high field strength elements (e.g., Ta, Nb, Ti).

2006). This level of water saturation probably is too large to be observed in nature. Olivine is the major principal mineral of the upper mantle, which may store water in deep upper mantle (Hirschmann *et al* 2005). It is the major constituent of mantle peridotite ($\sim 60\%$ by mode) and may contain about 0.5 wt.% of H_2O (Hirschmann *et al* 2005). A value of ~ 0.9 wt.% of H_2O was reached in pure forsterite at 12 GPa (~ 360 km depth) and 1250°C (Smyth *et al* 2006). Addition of water into olivine increases its volume. For example, addition of 0.5 wt.% of H_2O to forsterite is equal to thermal expansion at zero pressure resulting from rising of temperature by 240°C (Smyth *et al* 2006). This has very important consequences, because after water saturation of the upper mantle peridotite it becomes buoyant. Possible upper mantle water capacity curves (Hirschmann *et al* 2005) are concave towards higher concentrations of water with maxima at depths of about 350–400 km. This feature leads to two regions of preferential melting of water saturated (or slightly oversaturated) mantle peridotite; at depths of about 410 km and 250 km (Hirschmann *et al* 2005) (figure 8b).

Basic assumptions and summary of the water saturation model of the STLIP origin (figure 9):

- Subduction-like geochemical trace element features in volumetrically dominated low-Ti rocks of the STLIP reflect water-saturated source;
- The water saturation was created through fast subduction and slab stagnation in the transition zone of mantle;

- Warmed slabs up to ambient temperature of the transition zone released water fluid into transition zone mantle;
- Water saturation of the transition zone either resulted in partial melting or in advection of the mantle through 410 km discontinuity;
- Further advection of the mantle peridotite resulted in melting at about 250 km depths right beneath the thick cratonic lithosphere;
- Low-Ti melts were derived from 250 km deep region of melting by a drainage event.

7. Discussion

The large volume of basalt in the STLIP is usually considered as a proof of mantle rocks overheated by up to 300°C (a mantle plume) at a source of melting (e.g., Campbell *et al* 1992). Recent studies suggest, however, that significant amounts of the fusible material (e.g., eclogite) should be involved in melting (e.g., Yasuda and Fujii 1998; Lin and van Keken 2005; Sobolev *et al* 2007), though this may be still insufficient to produce the enormous volume of the STLIP. Keays (2005) argued that to supply high PGE concentrations in the STLIP a high degree of partial melting ($> 25\%$) is required for extraction of PGE from mantle sulphides, and that requires high temperature and hence a plume. Eclogitic recycled oceanic crust as the source of the PGE can be ruled out because of extremely low PGE concentration in MORBs (e.g., Bézou *et al* 2005) in comparison to mantle peridotites (e.g., Pearson *et al* 2004).

Figure 10. Comparison of the high Mg-number dolerite sample 887 of the low-Ti-2 series with the parental melt compositions of six different volcanoes, including Klyuchevskoi volcano, along the frontal arc of Kamchatka (100–180 km above the subducting slab). Other high Mg-number samples of the Angara–Taseevskaya sills show the same trace-element spectra (figure 4) and not plotted for the sake of simplicity. Data for parental melts of Kamchatka are plotted after Portnyagin *et al* (2007). Average of high Mg-number basalts of the Klyuchevskoi volcano (Dorendorf *et al* 2000) is also plotted to show that parental and crystallized melts exhibit the same trace-element patterns. Rb, Ta, Pb were not analyzed by Portnyagin *et al* (2007) and hence excluded from the diagram.

The plume model for the STLIP has been criticized on the basis of subsidence/uplift history (Czamanske *et al* 1998). Saunders *et al* (2005) advocated an uplift, which is now hidden beneath Mesozoic sedimentary cover of the west Siberian basin. Recent calculations including more realistic lithospheric structure have shown that uplift is not a necessary outcome for a plume (Burov and Guillou-Frottier 2005).

It has been claimed that major, trace element, and radiogenic isotope data for the STLIP are in general agreement with the plume model, and that these data provide evidence of fractional crystallization of primary plume high-Ti magma and significant assimilation of continental crust material to produce low-Ti basaltic suite (Wooden *et al* 1993; Ryabchikov *et al* 2001; Medvedev *et al* 2003; Reichow *et al* 2005). However, such interpretation seems unable to explain the sharp change from high-Ti to low-Ti basalt chemistry (e.g., figure 3c, d), and provides no place for an OIB-type component in mixing models for origin of the low-Ti melts (e.g., figure 6b), the volumetric insignificance of the high-Ti basalt series in most regions of the STLIP, or the lack of continuous trends between high-Ti basalts, low-Ti basalts and presumed assimilated continental crust (Fedorenko *et al* 1996; Ivanov

and Balyshev 2005; Ivanov 2007). Here we suggest that voluminous low-Ti type of magmas are sublithospheric in origin and can be produced by large-scale water saturation of the upper mantle due to, first, water saturation of the transition zone through subduction, second, dewatering the transition zone (figure 9). However, we note that delamination of the lower crust (or basic crust recycling via plumes/diapirs) cannot be ruled out on the basis of geochemical data and should also be considered as a plausible model.

The general problem for the model, which relates low-Ti STLIP basalts with the deep water-bearing layer, is that it requires incomplete slab dewatering during subduction. In depth interval between about 200 and 250 km water can be stored in nominally unhydrous omphacite, garnet, rutile (Katayama *et al* 2006) and olivine (Smyth *et al* 2006). The higher the rate of subduction and the thicker the slab, the more water preservation in the slab can be expected. With respect to the STLIP, a high rate of subduction of Mongolo-Okhotsk paleoslab was argued by Zorin *et al* (1998). Ivanov and Balyshev (2005) suggest that dewatering of the transition zone could occur because of conductive heating of the subducted slab to ambient temperature of the upper mantle (see also figure 8). Dewatering leads to saturation of the overlying upper mantle with water, decreasing its melting point and triggering voluminous melting. It is important to note that transport of material from the transition zone elevates temperatures in the sublithospheric mantle that together with saturation of the upper mantle with water makes it more buoyant and less viscous; these are two factors which are important for the delamination model (see above section 4.2). Hence our model and delamination model can act together. This possibility requires special consideration in future. Some of the aspects of our model find support in experimental petrology, others, probably, remain speculative (see section 6.4 above).

Presence of primary magmatic water-bearing minerals is also expected in the melts derived from water-bearing source. It is known that amphibole and biotite was found in the Noril'sk-I intrusion (Renne 1995). Reports of the magmatic biotite are quite common for many mafic and ultramafic intrusive and extrusive rocks within the STLIP (e.g., Fedorenko and Czamanske 1997 for meimechite in the Maymecha-Kotuy province; Reichow *et al* 2002 for olivine gabbro in the west Siberian basin; Ivanov 2007 for dolerite in the Angara–Taseevskaya Syncline). It is worth mentioning that amphibole and mica in basalts are rare minerals even in modern subduction-related volcanic provinces. For example, in the Kamchatka subduction system, amphibole- and mica-bearing basalts were

found mainly (only?) within perpendicular to arc fault systems; the Aleut-Kamchatka and Malko-Petropavlovsk fault systems. There they represented by moderately and high-alkaline basalts of subvolcanic bodies and volcanic bombs (Perepelov *et al* 1986; Melekestsev *et al* 1991; Volynets *et al* 1997). In the rear volcanic arc of the Kamchatka system, amphibole was found only in high-K shoshonitic basalts (Melekestsev *et al* 1991). STLIP melts are mainly low in potassium that probably prevents crystallization of the amphibole and mica. Evidence for high oxygen fugacity (and hence high H₂O or CO₂) in the Angara-Taseevskaya melts comes from the early crystallization of magnetite (see section 5) (Feoktistov 1961, 1978).

Direct evidence of water in fluid and melt inclusions in minerals such as olivine of the STLIP is not currently available. Thus we try indirect comparison through trace-element data. It can be seen that the high Mg-number dolerites show good agreement in practically all trace-elements with parental melts of the frontal arc of Kamchatka (calculated from melt inclusion analyses by Portnyagin *et al* 2007) (figure 10). The parental melts and the source mantle beneath Kamchatka are characterized by 1.8–2.6 wt.% and 0.1–0.4 wt.% of H₂O, respectively (Portnyagin *et al* 2007).

In the context of our model, the STLIP is a kind of back-arc volcanism. This is not a new idea. Cox (1978) proposed such an idea for explanation of Parana, Karro and Beacon (Ferrar and Kirkpatrick) traps that erupted within southern part of Gondwana and assumed that involvement of wet mantle could be viable for Deccan Traps, Siberian Traps (STLIP), North Atlantic Province and Columbia River Plateau. With regard to STLIP, Nikishin *et al* (2002) wrote ‘*Considering down-flow of the mantle at deep-reaching subduction zones, some flood basalts perhaps be regarded as some sort of back-arc magmatic provinces*’.

Previously, researchers tried to find trace element similarities between STLIP basalts and intraplate oceanic basalts such as those from Ontong Java and Hawaii (e.g., Lightfoot *et al* 1993; Wooden *et al* 1993; Reichow *et al* 2005). However, comparisons with continental margin island-arc-type basalts may be more appropriate (Puffer 2001; Ivanov and Balyshev 2005; this study).

8. Conclusions

Dolerites of the Kansk–Taseevskaya basin are geochemical analogues of the low-Ti basalts from the classical Noril’sk lava sequence. The high-Mg dolerites of the Tolstomysovskii sill represent low-Ti-2 group, whereas low-Mg dolerites of the same

sill and that of Usol’skii sill represent low-Ti-1 group.

Major and trace element features of the low-Ti-1 group may be due to fractionation of olivine and plagioclase from primary low-Ti-2 group melts. However, primary melts of the Tolstomysovskii and Usol’skii sill were different in terms of Sr isotopes and some trace elements (e.g., Th/U).

The low-Ti-1 and low-Ti-2 dolerites exhibit notable similarities with island arc basalts and lower continental crust, respectively, whereas they are remarkably different from ocean island basalts and mid-ocean ridge basalts.

The preferred interpretation of the origin of the dolerites is connected with a model of upper mantle water-saturation via subduction-related processes (figure 9). Striking similarities of the low-Ti rocks all over the Siberian Traps Large Igneous Province suggest a similar origin for all these rocks.

Acknowledgements

This work is dedicated to the memory of G D Feoktistov, who initiated this study. Various aspects of this paper have been discussed with V G Belichenko, L T Elkins-Tanton, G R Foulger, Yu A Zorin, A B Perepelov. In particular, we thank L T Elkins-Tanton for useful suggestions on the reworking of an earlier version of the paper. We thank S P Verma and I S Torres-Alvarado for giving SINCLAS program and guiding through its installation. H C Sheth and G R Foulger provided useful comments in reviewing the paper. E P Chebykin, A P Chebykin and M E Markova are thanked for help with ICP-MS analytical work. We thank M N Maslovskaya and V M Savatenkov for conducting part of rubidium–strontium isotope measurements. The work is supported by the Russian Foundation for Basic Research (grants 05-05-64477, 05-05-64281) and by personal grant MK-1588.2006.5 from the President of the Russian Federation for D.E.I.
