Five watersheds (W1, W2, W3, W4 and W5) in the upper Indus basin were chosen for detailed studies to understand the influences of geomorphology, drainage basin morphometry and vegetation patterns on hydrology. From the morphometric analysis, it is evident that the hydrologic response of these watersheds changes significantly in response to spatial variations in morphometric parameters. Results indicate that W1, W2 and W5 contribute higher surface runoff than W3 and W4. Further, the topographic and land cover analyses reveal that W1, W2 and W5 generate quick runoff that may result in flooding over prolonged rainy spells. A physically based semi-distributed hydrologic model (soil and water assessment tool, SWAT) was used for simulating the hydrological response from the watersheds. As per the simulations, W5 watershed produces the highest runoff of 11.17 mm/year followed by W1 (7.9 mm/year), W2 (6.6 mm/year), W4 (5.33 mm/year) and W3 (4.29 mm/year). Thus, W5 is particularly more vulnerable to flooding during high rain spells followed by W1, W2, W4 and W3, respectively. Synthetic unit hydrograph analysis of the five watersheds also reveals high peak discharge for W5. The simulated results on the hydrological response from the five watersheds are quite in agreement with those of the morphometric, topographic, vegetation and unit hydrograph analyses. Therefore, it is quite evident that these factors have significant impact on the hydrological response from the watersheds and can be used to predict flood peaks, sediment yield and water discharge from the ungauged watersheds.

1. Introduction

At the global level, flooding is the single most destructive type of natural disaster that strikes humans and their livelihoods around the world (UN 2004). The impacts of flood hazards on a global scale are enormous (Ahern *et al* 2005; Berz *et al* 2001; Hajat *et al* 2003; Jonkman 2005; Jonkman and Vrijling 2008). Flooding is responsible for more than one-third of the total estimated costs incurred due to disasters and is responsible for two-thirds of the people affected by natural disasters (Coates 1999; Jonkman and Kelman 2005;

Jonkman 2005; Munich Re 2007; UN 2004). Spatial and temporal dimensions of this threat have driven the current international and national concerns on how to lessen the consequences of flood hazards and human losses. In the last decade, there have been catastrophic flooding events all over the globe. The main reasons for the observed increase in flood disasters are an increase in the global temperature due to the effects of climate change (IPCC 2007); population growth and migration of population to coastal areas and river valleys; overexploitation of natural resources, deforestation, growing urbanization and uncontrolled land

use change. Flooding is not restricted to the least developed nations, but also occurs in a devastating manner in the most developed and industrialized countries of the world. However, it is the citizens of the least developed nations that suffer the highest toll from flooding. India, being one of the developing countries where floods and other natural disasters are one of the serious geo-hazards, has witnessed alarmingly increased floods in recent times due to number of complex factors related to topography, geology, climate and human activity. About 40 million hectares or nearly 1/8th of India's geographical area is flood-prone (Bapalu and Sinha 2005). Among the physiographic divisions of India, the Himalayas have the greatest sub-areal maximum relief, torrential rainstorms, frequent cloud bursts and a history of floods augmented by melting glaciers and river action. The floods thus pose a major physical threat to the sustainable development in the Himalayas (Jack 2004). The available data suggests that during the period 1954–1990, more than ₹ 2700 billion were spent on the flood control measures in India, but the annual flood damage increased by nearly 40 times and the annual flood affected areas increased by 1.5 times in this period (Agarwal and Narain 1996). Among the various hazard-prone Himalayan states of India, Jammu and Kashmir is more vulnerable to almost all the hazards. The historical records reveal that the Kashmir Himalayan region has suffered heavy casualties and loss of property due to floods, avalanches and other hydrometeorological disasters.

Flooding results from climatological events such as excessive and/or prolonged rainfall, including snow and ice melt, cloud burst, failure of dams and storm surges. Floods can be intensified by factors associated either with the catchment itself or with the drainage network and stream channels (Ward and Robinson 2000). Furthermore, there exist a number of factors that can further affect the process of flooding (Gardiner 1981). Such factors can be human or physical or both, and will exert dominant controls to either intensify or ameliorate a flooding event. Topography is recognized as a first-order control on the hydrological response of a catchment to rainfall (Brasington and Richards 1998) and is a major determinant for flood inundation (Bates and De Roo 2000). Similarly, morphological characteristics such as stream order, drainage density, channel slope, relief, length of overland flow, stream frequency and other morphological aspects of watershed are important in understanding the hydrology of the watershed (Chow 1964; Strahler 1964; Ward and Robinson 2000; Hudson and Colditz 2003). Runoff response of the watershed is different for different slopes, shapes, lengths, widths and areas of watershed.

Natural features such as land use and land cover, soil and geology that have significant influence upon the characteristics of a catchment hydrograph, need to be considered, for understanding flood mechanisms. This is largely related to the permeability, transmissibility and water storage of the catchment (Barry and Chorley 1998; Robinson *et al* 2000; Ward and Robinson 2000). Deforestation can lead to increased risk and magnitude of flood inundation (Bosch and Hewlett 1982; Arnell 2002). It is therefore very important to quantify the geomorphic, morphological and topographic characteristics of a watershed accurately in order to aid in analysing the hydrologic response of watersheds.

Even though there is growing interest in carrying out research on natural disasters among geoscientists, there is still a significant gap in our understanding of the factors associated with flood hazard vulnerability (Beven 1989). This research therefore addresses the fundamental scientific question of assessing the geologic and hydrological factors that make a drainage basin more or less prone to flooding. In this research, an integrated analysis of the hydrological, morphological and geomorphometrical properties of five watersheds of the Jhelum River basin facilitated a better understanding of the flooding problem and its associated processes. The advancement in the field of satellite remote sensing, geographic information system (GIS), simulation modelling and advanced field observation techniques have facilitated a better understanding of the geomorphological and geological influences on hydrology. Remote sensing data was used to generate up-to-date information about different hydrological and geomorphological parameters. Simulation models and geospatial techniques were used to simulate the hydrological processes. Thus, the findings can be of tremendous practical use in planning flood management and mitigation strategies. The contents of this paper are organized into various sections such as introduction, study area, methods, results, discussion and conclusions.

2. Study area

The Jhelum basin is elongated in shape and bounded between the Zanaskar (Greater Himalayas) and Pir Panjal mountain ranges between 33° 21' 52"–34° 41' 33" N latitude and 74° 07' 55"–75° 29' 57" E longitude. River Jhelum passes largely along the middle of the Kashmir valley through the alluvium of its own deposition. The basin is the recipient of the entire drainage of the valley and is known in Kashmir by the name 'VYATH'. The river comprises fairly developed streams as well as

Figure 1. 3-D view of five watersheds.

tiny rivulets with quite remarkable variations in the drainage and catchment characteristics. The Jhelum basin has 24 tributaries and some of them drain from the slopes of the Pir Panjal range and join the river on the left bank; while others flow from the Himalayan range and join the river on the right bank. So, the Jhelum basin has 24 catchments and these have been subdivided into 60 subcatchments. The hydrographic features and drainage characteristics of Jhelum river system show that the frequency of floods has been very high ever since the valley assumed its present form. There have been almost more than 25 major floods and mean expectancy being 1 in 4.3 years (Moonis *et al* 1975). The valley being saucer-shaped with steep mountain slopes around, any heavy rain spell for duration of 1–2 days can cause serious floods (Dhar *et al* 1982). In general, the layout of Kashmir valley is such that it is highly prone to flooding. Also, the growth of human population and horizontal expansion of settlements and encroachments on the water courses, reclamation of low-lying areas for agriculture, channelizing of rivers, construction of roads along river banks and urbanization of the flood plains, have aggravated flood risk in the Jhelum basin. In order to accomplish the research objectives, five watersheds in the upstream of Jhelum basin, herein referred as W1 (long. 74°32′–74°36′E, lat. 33°40′–33°43′N), W2 (long. 74°32′–74°33′E, lat. 33°39′–33°40′N), W3 (long. 74°43′–74°46′E, lat. 33°41′–33°44′N), W4 (long. 74°42′–74°46′E, lat. 33°41′–33°44′N) and W5 (long. 74°32′–74°35′E, lat. 33°33′–33°34′N), respectively, with an areal extent of 12.44, 11.97, 10.64, 11.58 and 10.83 km², respectively, were selected for detailed geomorphometric, hydrological, vegetation and climatological analyses. Figure 1 shows the three-dimensional (3-D) view of these five watersheds.

3. Methods

In order to accomplish the set research objectives, it is important to use a host of methods that includes the use of satellite remote sensing data, detailed field observations, hydrological data, digital elevation data, secondary/ancillary data, geospatial tools and simulation models. The details of the methodology adopted for accomplishing the research objectives are briefly discussed here.

3.1 Morphometry

Morphometry deals with the quantitative study of the area, altitude, volume, slope, profiles of the land and drainage basin characteristics of the

area concerned (Clarke 1966; Singh 1972a, 1972b; Strahler 1964). The application of geomorphic principles to understand and quantify environmental hazards such as flooding has led to a significant amount of research focused on identifying the relationships between basin morphometry and stream flooding (Patton 1988). In order to understand the geomorphological influences on the flooding, it is essential to study the morphometry and relate it to the hydrology of the basins (Rakesh 2000). Therefore, five watersheds with varied topographic, hydrologic, vegetation and physiographic setting were chosen for detailed morphometric analyses to understand the geomorphological and hydrological linkages.

However, it has been recognized that generating information about important basin parameters using traditional methods based on map measurements is labour-intensive and tedious. Other than a few parameters that can be easily measured from maps such as elevation and relief; measurement of more complex parameters such as stream length, drainage density, mean basin elevation and channel gradient for streams of different orders has been hampered by the amount of time that must be dedicated to extract these parameters from maps. Therefore, digital elevation models (DEM) in GIS environment were used to compute these morphometric characteristics with greater efficiency and accuracy. Geospatial techniques have gained significant importance over the last decade in their applications pertaining to drainage morphological characteristics (Band 1986; Mark 1988; Tarboton 1989; Lawrence and Jorgen 1993; Al-Wagdany and Rao 1994; Garbrecht and Martz 1997; Bhat and Romshoo 2008). The specific methods and steps followed for the generation of morphometric parameters are shown schematically in figure 2.

DEM is a representation of the continuous variation of relief over space and there are several possible methods for generating DEM. We used the existing 1:50,000 scale topographic maps with 20 m contours to generate DEM (Oky *et al* 2002). Due to nonavailability of high resolution stereo-imaging data for generation of DEM we preferred the existing topographic maps. DEMs at 20 m resolution were generated from the digitized contours at watershed level using inverse distance weighted (IDW) interpolation technique (Burrough 1986). The process involved various steps (Band 1986; Tarboton and Shankar 1998; Bhat and Romshoo 2008). Various workers have used DEMs for extracting morphometric features (Mark 1988; Tarboton *et al* 1991, 1992; Tarboton 1997; Tarboton and Ames 2001). After the processing of the digital elevation models, the morphometric parameters were extracted using the mathematic formulations as described in table 1.

Figure 2. Flow chart of methodology used for morphometric analysis.

3.2 Synthetic unit hydrograph model

Clark (1945) pioneered hydrologic modelling approach with his unit hydrograph technique that uses three main components: time of concentration, a storage coefficient and a time-area histogram (Kull and Feldman 1998). Clark's synthetic unit hydrograph methodology involves the application of a unit excess rainfall (1 mm) over the watershed. The precipitation is conveyed to the basin outlet by a translation hydrograph and linear reservoir routing. For this purpose, the time of concentration value (T_c), the storage attenuation coefficient (R) and the time area histogram of the basin are necessary. The representative watersheds were subdivided into time-area increments by estimating the time of travel to various locations within the drainage network and constructing isochrones (Timothy *et al* 2000). The area representing each increment of time was measured, and the total volume represented by 1 inch of runoff from that increment was calculated. Dividing that by the time interval between the isochrones, it yields a volumetric flow rate, which is plotted against the travel time represented by the isochrones. In this way, the sequence of flows resulting from the instantaneous generation of 1 inch of runoff from all time-area increments is created. All these steps were carried

out in the GIS environment using DEM (Band 1986; Mark 1988).

3.3 Simulating hydrological processes

For understanding the interactions between the climatic, terrestrial, topographic and hydrological elements; hydrological response of the five ungauged watersheds was simulated using geospatial hydrological modelling approach. A number of research studies have been conducted under varied hydrological and geomorphological conditions using geospatial simulation models to quantify the hydrological processes at various spatial scales (DeVantier and Feldman 1993; Olivera and Maidment 1996; Jain and Sinha 2003; Gorokhovich *et al* 2000; Saghafian *et al* 2000). In order to quantify the hydrological processes in the five representative watersheds, we used GIS-based soil and water assessment tool (SWAT) model (Arnold *et al* 1998). SWAT is a physically based basin-scale, continuous time, distributed parameter hydrologic model that uses spatially distributed data on soil, land use, DEM and weather for hydrologic modelling and operates on a daily time step. Major model components include weather, hydrology, soil type, soil temperature and land management. For spatially explicit

Table 1. Equations and description of the morphometric parameters.

Parameters	Equation	Description
Watershed area (km ²)	$A = a \times n \times 10^{-6}$	a : cell area (m ²) n : number of watershed cells
Watershed perimeter (km)	$P = d \times n_p \times 10^{-3}$	d : cell size (m) n_p : number of watershed edge cells
Watershed length (m)	L_b	L_b = farthest distance from watershed ridge to outlet
Slope	$S = \frac{DE}{L}$	S = slope DE = difference in elevation L = length of the flow path
Stream length	$\bar{L}_u = \sum_{i=1}^N L_u$	$\bar{L}_u$ = mean length of channel L_u = stream-channel segment of order u
Stream length ratio	$RL = L_u / (L_u - 1)$	RL = stream length ratio L_u = the total stream length of order u $L_u - 1$ = the total stream length of preceding stream order
Drainage density	$D_d = \sum L_u / A_u$	D_d = drainage density L_u = total stream length A_u = basin area
Stream frequency	$F_s = \sum N_u / A_u$	F_s = stream frequency N_u = number of stream segments A_u = basin area
Bifurcation ratio	$R_b = (N_u) / (N_u + 1)$	R_b = bifurcation ratio N_u = number of stream segments
Length of overland flow	$L_g = 0.5 / D_d$	L_g = length of over flow D_d = drainage density
Form factor	$R_f = (A_u) / (L_b + 1)^2$	R_f = form factor A_u = basin area L_b = farthest distance from watershed ridge to outlet
Elongation ratio	$R_e = \frac{2}{\pi} \sqrt{\frac{A_u}{(L_b)^2}}$	R_e = elongation ratio $\pi = 3.14$ A_u = basin area L_b = farthest distance from watershed ridge to outlet
Circularity ratio	$R_c = 4\pi A_u / (A_u)^2$	R_c = circularity ratio A_u = basin area
Infiltration number	$I_f = D_d \times F_s$	I_f = infiltration number F_s = stream frequency

parameterization, SWAT subdivides watersheds into sub-basins based on topography, which are further subdivided into hydrologic response units (HRU) based on unique soil and land-use characteristics. SWAT can simulate surface runoff using either the modified SCS curve number (CN) method (USDA-SCS, 1972) or the Green–Ampt infiltration model based on an infiltration excess approach (Green and Ampt 1911) depending on the availability of daily or hourly precipitation data, respectively. The SCS curve number method was used in this study with daily precipitation data. Based on the soil hydrologic group, vegetation type and land management practice; initial CN values are assigned from the *SCS Hydrology*

Handbook (USDA-SCS 1972). SWAT updates the CN values daily based on changes in soil moisture. The excess water available after accounting for initial abstractions and surface runoff, using the SCS CN method, infiltrates into the soil. A storage routing technique is used to simulate the flow through each soil layer. SWAT directly simulates saturated flow only and assumes that water is uniformly distributed within a given layer. Unsaturated flow between layers is indirectly modelled using depth distribution functions for plant water uptake and soil water evaporation. Downward flow occurs when the soil water in the layer exceeds field capacity and the layer below is not saturated. The rate of downward flow is governed by

the saturated hydraulic conductivity. Lateral flow in the soil profile is simulated using a kinematic storage routing technique that is based on slope, slope length and saturated conductivity. Upward flow from a lower layer to the upper layer is regulated by the soil water to field capacity ratios of the two layers. The hydrological cycle, simulated by SWAT model, is based on the water balance equation given below:

$$SW_t = SW_0 + \sum_{i=1}^t (R_{\text{day}} - Q_{\text{surf}} - E_a - w_{\text{seep}} - Q_{\text{gw}}), \quad (1)$$

where SW_t is the final soil water content (mm H_2O), SW_0 is the initial soil water content on day i (mm H_2O), t is the time (days), R_{day} is the amount of precipitation on day i (mm H_2O), Q_{surf} is the amount of surface runoff on day i (mm H_2O), E_a is the amount of evapotranspiration on day i (mm H_2O), w_{seep} is the amount of water entering the vadose zone from the soil profile on day i (mm H_2O), and Q_{gw} is the amount of return flow on day i (mm H_2O).

3.3.1 SWAT model input data generation

Input data for SWAT was generated using remote sensing, field, lab and hydrometeorological observations. The various input parameters and the methods of their generation are described here.

3.3.1a Topographical data: Topographical information required for the SWAT model was generated from DEM. The various topographical parameters required for the model are drainage network, aspect, slope, flow length, flow accumulation, flow direction, etc. All these parameters were generated in a GIS environment using standard methods (Band 1986; Mark 1988; Tarboton *et al* 1991; Tarboton 2000).

3.3.1b Hydrometeorological data: SWAT model requires daily precipitation, maximum and minimum air temperature, solar radiation, wind speed and relative humidity. Therefore, 20-year time series of meteorological data (1979–1999) from six rainfall stations, one temperature recording station and one river gauging station observation station, was statistically analysed to generate these parameters as per the requirements of the model. A number of secondary hydrometeorological parameters required as input for the SWAT model were generated using different mathematical formulations as

shown in table 2. Table 3 shows the monthly averages of all the hydrometeorological variables used as input to the SWAT model for simulating the hydrological processes. To generate the spatial distribution of the rainfall in the study area, mean monthly and average yearly values were interpolated in GIS by using IDW method (Burrough 1986). This technique determines cell values using a linearly weighted combination of a set of sample points. The weightage is a function of inverse distance.

3.3.1c Land use/land cover data: Information about land use and land cover is vital for several land surface processes including hydrological and climatic processes and therefore it is a very important data input for the SWAT model. Remote sensing has a long and successful history of application in generating land use and land cover information on operational basis (Hansen *et al* 1996; Foody 2002). For generating land use/land cover information for the representative watersheds, we used Landsat ETM digital data of September 2001. The satellite image was pre-processed to rectify the geometric distortions in order to improve its interpretability (Lillesand and Kiefer 1987). Thirty ground control points were taken from different parts of the study area for precise geometric correction using Universal Transverse Mercator (UTM) coordinate system with World Geodetic System (WGS) 84 datum achieving root mean square error (RMSE) of 1.06 pixels. Various image enhancement techniques were also performed on the image for enhancing visual interpretability of the data. The corrected satellite data was then processed for land use and land cover classification using maximum likelihood supervised classification algorithm (Fu 1976). While choosing various training samples for known land cover types, various image enhancement techniques were applied for homogenous and better choice taking into consideration the ground truth information. The land use and land cover map was validated in the field to determine its accuracy. The accuracy estimation is essential to assess reliability of the classified map. The ideal number of sample points chosen (64) for assessing the accuracy of the classification map was determined using binomial probability theory (Jensen 1996).

3.3.1d Soil data input: The information about soil is very vital for estimating the hydrological response at the watershed scale. The SWAT model requires detailed soil information on the type, properties and other geophysical characteristics. The methods employed for generating the

Table 2. Equations and description of the meteorological parameters used as input for the SWAT model.

Parameters	Formulae	Description
TMPMX (Mean daily maximum temperature ($^{\circ}\text{C}$))	$\mu mx_{\text{mon}} = \frac{\sum_{d=1}^N T_{\text{mxmon}}}{N}$	μmx_{mon} = mean daily maximum temperature T_{mxmon} = daily maximum temperature N = total number of daily maximum temperature records
TMPMIN (Mean daily minimum temperature ($^{\circ}\text{C}$))	$\mu mn_{\text{mon}} = \frac{\sum_{d=1}^N T_{\text{mnmon}}}{N}$	μmn_{mon} = mean daily minimum temperature T_{mnmon} = daily minimum temperature N = total number of daily minimum temperature records
TMPSDMX (Standard deviation for daily maximum temperature ($^{\circ}\text{C}$))	$\sigma = \sqrt{\frac{\sum_{d=1}^N (T_{\text{mxmon}} - \mu mx_{\text{mon}})^2}{N - 1}}$	σ = standard deviation for daily maximum temperature T_{mxmon} = daily maximum temperature μmx_{mon} = mean daily maximum temperature N = total number of daily maximum temperature records
TMPSDMIN (Standard deviation for daily minimum temperature ($^{\circ}\text{C}$))	$\sigma = \sqrt{\frac{\sum_{d=1}^N (T_{\text{mnmon}} - \mu mn_{\text{mon}})^2}{N - 1}}$	σ = standard deviation for daily minimum temperature μmn_{mon} = mean daily minimum temperature T_{mnmon} = daily minimum temperature N = total number of daily minimum temperature records
PCPMM (Mean daily precipitation (mm))	$R_{\text{mon}}^- = \frac{\sum_{d=1}^N R_{d,\text{mon}}}{\text{yrs}}$	R_{mon}^- = mean monthly precipitation (mm H_2O) $R_{d,\text{mon}}$ = daily precipitation N = total number of records in month yrs = number of years of daily precipitation
PCPSTD (Standard deviation for daily precipitation (mm))	$\sigma_{\text{mon}} = \sqrt{\frac{\sum_{d=1}^N (R_{d,\text{mon}} - R_{\text{mon}}^-)^2}{N - 1}}$	σ_{mon} = standard deviation for daily precipitation in a month (mm H_2O) $R_{d,\text{mon}}$ = amount of precipitation for record d in month (mm H_2O) R_{mon}^- = average precipitation for the month (mm H_2O) N = total number of daily precipitation
PCPSKW (Skew coefficient for daily precipitation)	$g_{\text{mon}} = \frac{N \left(\sum_{d=1}^N R_{d,\text{mon}} - R_{\text{mon}}^- \right)^2}{(N - 1)(N - 2)(\sigma_{\text{mon}})^2}$	g_{mon} = skew coefficient for precipitation in the month N = total number of daily precipitation $R_{d,\text{mon}}$ = amount of precipitation (mm H_2O) R_{mon}^- = average precipitation for the month (mm H_2O) σ_{mon} = standard deviation for daily precipitation (mm H_2O)

PR_W1 (Probability of a wet day following a dry day)	$P_i \left(\frac{W}{D} \right) = \frac{\text{days}(W/Di)}{\text{days}_{\text{dry}i}}$	$P_i(W/D)$ = probability of a wet day following a dry day W/Di = number of times a wet day followed a dry day in a month $\text{days}_{\text{dry}i}$ = number of dry days in month i during the entire period of record. A dry day is a day with 0 mm of precipitation. A wet day is a day with > 0 mm precipitation
PR_W2 (Probability of a wet day following a wet day)	$P_i \left(\frac{W}{W} \right) = \frac{\text{days}(W/Wi)}{\text{days}_{\text{wet}}}$	$P_i(W/W)$ = probability of a wet day following a wet day in a month W/Wi = number of times a wet day followed a wet day in a month for the entire period of record days_{wet} = number of wet days in a month during the entire period of record
PCPD (Average number of days of precipitation)	$d_{\text{weti}}^- = \frac{\text{days}_{\text{weti}}}{\text{yrs}}$	d_{weti}^- = average number of days of precipitation $\text{days}_{\text{weti}}$ = number of wet days in month i during the entire period of record yrs = number of years of daily precipitation It represents maximum half hour rainfall in entire period of record for a month (mm H ₂ O). This value represents the most extreme 30-min rainfall intensity recorded in the entire period of record
RAINHHMX (Maximum 0.5 hour rainfall)		
SOLARAV (Average daily solar radiation (MJ/m ² /day))	$\mu rad_{\text{mon}} = \frac{\sum_{d=1}^N H_{\text{day.mon}}}{N}$	μrad_{mon} = mean daily solar radiation for the month (MJ/m ² /day) $H_{\text{day.mon}}$ = total solar radiation reaching the earth's surface for day d in a month (MJ/m ² /day) N = total number of daily solar radiation records for a month
DEWPT (Average daily dew point temperature)	$\mu dew_{\text{mon}} = \frac{\sum_{d=1}^N T_{\text{dew.mon}}}{N}$	μdew_{mon} = mean daily dew point temperature for the month (°C) $T_{\text{dew.mon}}$ = dew point temperature for day d in a month (°C), N = total number of daily dew point records for a month
WINDAV (Average daily wind speed)	$\mu wnd_{\text{mon}} = \frac{\sum_{d=1}^N \mu_{\text{wnd.mon}}}{N}$	μwnd_{mon} = mean daily wind speed for the month (m/s) $\mu_{\text{wnd.mon}}$ = average wind speed for day d in a month (m/s), N = total number of daily wind speed records for month

soil map involved field observation, lab analysis and the remote sensing data (Khan and Romshoo 2008). Visual interpretation of Landsat ETM September 2001 image was carried out and different soil classes delineated on the basis of tone, texture, shape and associated land cover types and various other image elements that aided soil interpretation. A series of field surveys were conducted for validation of identified soil classes from the satellite image. Soil samples from each identified classes were collected for the soil texture analyses in the lab. Composite soil samples up to 15 cm depth were collected for each soil class. About 2–3 samples were collected from each identified soil class for the lab analysis for determining the soil texture. In all, 36 composite soil samples were analysed for soil texture using pipette method (Day 1965). This method involves two steps: (a) dispersion; and (b) fractionation. The texture of the soil was determined from the relative proportions of sand, silt and clay that it contained, using the soil textural triangle (Toogood 1958). All the spatial and non-spatial information generated, as described above, was integrated into a geospatial soil database for use in the SWAT model.

4. Results and discussion

The research involved a host of multidisciplinary methods and required the integrated use of

satellite data, field observations, simulation models and geospatial analysis to accomplish the research objective. The myriad of results obtained on geomorphology, topography, hydrology, land use/land cover and simulation modelling, are therefore analysed and discussed chronologically under the following headings.

4.1 Morphometric analysis

The values of various morphometric parameters estimated using the methods described in table 1 are shown in table 4. The hydrological significance of these parameters is discussed here.

4.1.1 Stream order (U)

The primary step in drainage-basin analysis is to designate stream orders (Horton 1945). As per the Strahler (1964) ordering scheme, all the five watersheds are 4th-order streams. Figure 3 shows the stream orders of the five watersheds. Higher stream order is associated with greater discharge and higher velocity of the stream flow.

4.1.2 Stream number (N_u)

The count of stream channels in its order is known as stream number (Horton 1945). Results as shown in table 4 indicate that W1 has 66,

Figure 3. Drainage pattern and stream orders of the five watersheds.

12, 3 and 1 stream segments in 1st, 2nd, 3rd and 4th orders, respectively; W2 has 36, 11, 3 and 1 in 1st, 2nd, 3rd and 4th orders, respectively; W3 has 40, 7, 2 and 1 in 1st, 2nd, 3rd and 4th orders, respectively; W4 has 48, 7, 2 and 1 in 1st, 2nd, 3rd and 4th orders, respectively and the W5 has 168, 36, 9 and 1 in 1st, 2nd, 3rd and 4th orders, respectively. The number of the stream segments decreases as the order increases. A higher stream number indicates lesser permeability and infiltration. Stream number is directly

proportional to size of the contributing watershed and to channel dimensions. The maximum frequency in case of first order is unambiguous in all cases. Figure 4 shows the linear relationship between the number of streams and the stream orders in all the five watersheds. It means that the number of streams usually decreases in geometric progression as the stream order increases. The variations in rock structures of watersheds are responsible for inequalities in stream frequencies of each order.

Figure 4. Stream order–stream number relation of the five watersheds.

4.1.3 Stream length (L_u)

Results show that the total length of stream segments is maximum in case of first-order streams. It decreases as order increases in case of W1, W3 and W5 as shown in figure 5. W2 and W4 do not show geometric relationship and show variation from order to order as indicated in figure 5. This discrepancy is due to variations in relief and lithology over which these stream segments occur.

4.1.4 Drainage density (D_d)

The drainage density of W1, W2, W3, W4 and W5 are 3.01, 2.83, 2.62, 2.72 and 4.50, respectively as shown in table 4. The higher drainage density of W1 (3.01 km/km²), W2 (2.83 km/km²) and W5 (4.5 km/km²) indicates that the regions under these watersheds are composed of impermeable subsurface material, sparse vegetation and mountainous relief. The lower drainage density of

Figure 5. Stream order–stream length relation of the five watersheds.

W3 (2.62 km/km²) and W4 (2.72 km/km²) reveals that these watersheds are composed of permeable subsurface material, good vegetation cover and low relief as compared to other three watersheds, which results in more infiltration capacity and can be good sites for ground recharge sites. In general, the hydrology of watershed changes significantly in response to the changes in the drainage density (Yildiz 2004). A high drainage density reflects a highly dissected drainage basin with a relatively rapid hydrological response to rainfall events, while a low drainage density means a poorly drained basin with a slow hydrologic response (Melton 1957). Overall drainage density results indicate that W1, W2 and W5 contribute more surface

runoff to the streams than W3 and W4. Carlston (1963) observed that there is a very close relationship between drainage density and mean annual

Table 5. Topographic parameters of the five watersheds.

Watershed	Minimum elevation (metres)	Maximum elevation (metres)	Average slope (degrees)
W1	2881	4680	26.39
W2	2931	4560	26.39
W3	2100	2700	11.17
W4	2108	2700	15.83
W5	3480	4367	27.00

flood. Therefore, W5 having highest drainage density followed by W1 and W2 are more prone to flooding than the other two watersheds.

4.1.5 Stream frequency (F_s)

The stream frequencies of W1, W2, W3, W4 and W5 are 6.59, 6.52, 4.70, 5.01, and 19.74 km^{-2} , respectively (table 4). Stream frequency is related to permeability, infiltration capacity and relief

of watersheds (Montgomery and Dietrich 1989, 1992). W5 shows very high stream frequency (19.74 km^{-2}), followed by W1 (6.59 km^{-2}) and W2 (6.52 km^{-2}). These values indicate that W5 has rocky terrain and very low infiltration capacity among all of the five watersheds. Further, it is noted that stream frequency decreases as the stream number increases. Stream frequencies of W3 (4.70 km^{-2}) and W4 (5.01 km^{-2}) reveal that these watersheds are covered by vegetation and have very

Figure 6. Elevation maps of the five watersheds.

good infiltration capacity. Overall, the results of stream frequency reflect early peak discharge in case of W1, W2 and W5 that may result in flash-floods while the discharge from W3 and W4 would take time to peak because of low runoff rates.

4.1.6 Bifurcation ratio (R_b)

The mean bifurcation ratios of W1, W2, W3, W4, and W5 are 4.17, 4.13, 3.74, 4.12 and 5.89, respectively. The bifurcation ratio will not be precisely the same from one order to the next, because of possibility of variations in watershed geometry

and lithology, but tends to be a constant throughout the series. The high bifurcation ratio indicates early hydrograph peak with a potential for flash flooding during the storm events (Rakesh *et al* 2000). Therefore, higher bifurcation ratio for W5 watershed indicates its vulnerability to flooding.

4.1.7 Length of overland flow (L_g)

Length of overland flow is one of the most important independent variables affecting both hydrologic and physiographic development of drainage basins (Horton 1932). From table 4, it can be seen

Figure 7. Slope map of the five watersheds.

that lengths of overland flow of W1, W2, W3, W4 and W5 watersheds are 0.17, 0.18, 0.19, 0.18 and 0.11, respectively. The values of length of overland flow of watersheds, W1 (0.17), W2 (0.18), W3 (0.19) and W4 (0.18) indicate gentler slopes and longer flow paths than W5 (0.11). The values also indicate that runoff will take very less time to reach outlet in case of W5 followed by W1, W2, W4 and W3, respectively. Thus, W5 shall be more vulnerable to the flash flooding compared to the other watersheds.

4.1.8 Form factor (R_f)

The form factor values of W1, W2, W3, W4 and W5 are 0.41, 0.41, 0.61, 0.41 and 0.72, respectively as shown in table 4. It indicates that W5 is circular with higher value of 0.72 whereas remaining four watersheds are elongated. Watershed morphology has profound impact on watershed hydrology (Tucker and Bras 1998). This again reaffirms that W5 will have quick, though lower, hydrograph peak compared to the other watersheds.

4.1.9 Elongation ratio (R_e)

Table 4 shows that the elongation ratio of the five watersheds varies from 0.62 to 0.88. W5 has highest values of 0.88 followed by W1 (0.79), W2 (0.75), W3 (0.71) and W4 (0.62). Results of elongation ratio indicate that W5 is circular, W3 is oval and remaining (W1, W2 and W4) watersheds are less-elongated. The impact of varied watershed morphology on the hydrological response shall be similar as that of the form factor discussed here (Strahler 1964).

4.1.10 Ellipticity index (E_i)

W1, W2, W3, W4 and W5 have ellipticity indices of 7.17, 7.68, 5.19, 7.65 and 4.49, respectively

(table 4). The ellipticity index provides similar insights about the relationship between morphometry and hydrology as other shape-related parameters. Lower values indicate that the runoff from the catchment drains quickly into the channels and thereby, depending upon the total quantum of the precipitation, the channels may swell or even overflow resulting in flooding downstream areas.

4.1.11 Circulatory ratio (R_c)

The circulatory ratios of W1, W2, W3, W4 and W5 are 0.57, 0.46, 0.35, 0.44 and 0.87, respectively (table 4). Circulatory ratio results from the five watersheds show that W1 (0.57) and W5 (0.87) are more or less circular and are characterized by high to moderate relief. The remaining watersheds (W2, W3 and W4) indicate that they are elongated and are characterized by moderate to low relief.

All the above shape-related parameters significantly influence the hydrological response of the watersheds as basin-shaped and the arrangement of stream segments combine to influence the size and shape of flood peaks (Ward and Robinson 2000). As such, W5 has high flood peaks followed by W1 and W2 as compared to W3 and W4.

4.1.12 Infiltration number (If)

Infiltration number plays a significant role in observing the infiltration character of basin. It is inversely proportional to the infiltration capacity of the basin. The infiltration numbers of W1, W2, W3, W4 and W5 are 19.94, 18.45, 12.34, 13.65 and 88.86, respectively (table 4). The results reveal that W5 has very low infiltration capacity, W1 and W2 have low infiltration capacity and W3 and W4 have high infiltration capacity. It indicates that runoff will be very high in case of W5 followed by W1 and

Table 6. Distribution of slope classes in the five watersheds.

Slope classes	Area (km ²)				
	W1	W2	W3	W4	W5
0–5	0.88	0.76	3.14	3.63	0.41
5–10	0.97	0.88	2.57	1.46	0.56
10–15	1.21	1.33	2.86	2.29	0.88
15–20	1.35	1.46	1.14	1.60	1.15
20–25	1.41	1.44	0.58	1.18	1.21
25–30	1.42	1.62	0.22	0.62	1.44
30–35	2.09	1.63	0.09	0.50	1.44
35–40	1.39	1.30	0.03	0.24	1.22
40–45	1.00	0.75	0.01	0.05	1.13
45–90	0.72	0.80	0.00	0.01	1.40

W2 during rain spells. It means that downstream areas of W5 shall be flooded very quickly followed by W1 and W2.

4.2 Topographic analysis

The topographic parameters of W1, W2, W3, W4 and W5 have been calculated using DEM

(Tarboton 1989). The minimum elevation of W1, W2, W3, W4 and W5 ranges between 2100 and 3480 m a.m.s.l, and the maximum elevation of W1, W2, W3, W4 and W5 ranges between 2700 and 4680 m a.m.s.l, as shown in table 5 and figure 6. The average slope of watersheds varies from 11.17° to 27° . W5 has an average slope of 27° followed by W1 and W2 (26.39°), W3 (11.17°) and W4 (15.83°). Higher average slope for W1, W2

Figure 8. Area-elevation distribution in the five watersheds.

and W5 is an indication of generating quick runoff during rains or storm events (Tucker and Bras 1998). The different slope categories of each watershed are shown in figure 7. Catchment morphology and hydrology are strongly influenced by hillslope

processes (Tucker and Bras 1998). Slope/area relation analysis as shown in table 6 indicates that W1, W2 and W5 have large areas under high slopes compared to W3 and W4, which also reaffirms that these watersheds generate higher runoff during

Figure 9. Instantaneous unit hydrographs results of the five ungauged watersheds.

rainfall events. These watersheds are therefore highly prone to flooding than the other two watersheds. There is a significant relationship between the slope and the contributing area (Willgoose 1996). Area-elevation analysis for each of these watersheds, as shown in figure 8 indicates that W1 and W2 have smaller areas under higher elevations compared to W3, W4 and W5. This again indicates that quick runoff may be generated from these watersheds that may result in flooding over prolonged rainy spells.

4.3 Synthetic unit hydrograph analysis

Instantaneous unit hydrograph results of all five ungauged watersheds are shown graphically in figure 9 and tabulated in table 7. The results indicate that W5 has high peak discharge of 31.98 cusecs and least time to peak of 224 minutes followed by W1 of peak discharge of 31.74 cusecs and time to peak of 240 minutes and W2 peak discharge of 25.22 cusecs and time to peak of 295 minutes. While W3 has a peak discharge of 16.74 cusecs and time to peak of 372 minutes followed by W4 which has a peak discharge of 17.09 cusecs and time to peak of 483 minutes. The results clearly reveal that W5 with highest discharge potential and lower time to hydrograph peak, is more prone to flooding as compared to other watersheds. Results also reaffirm that W1 is almost equally prone to large surges of water discharge and consequent flooding.

4.4 Hydrological model simulations

In order to simulate the hydrological response (runoff) from these five watersheds using SWAT, various input parameters related to hydrometeorology, land use/cover data, topography, soil, etc. were generated as already described. The analyses of these input parameters are discussed here.

4.4.1 Hydrometeorological data analysis

Hydrometeorological data were analysed to generate the spatial distribution of the necessary input

Table 7. Time-to-peak and peak discharges from the five watersheds.

Watershed	Time to peak (minutes)	Peak discharge (cusecs)
W1	240	31.74
W2	295	25.22
W3	372	16.74
W4	483	17.09
W5	224	31.98

parameters for SWAT model. Spatial distribution of hydrometeorological data is required for the simulation of hydrological and meteorological response at the watersheds scale using distributed hydrological and climate models (Hamlet and Lettenmaier 1999). Estimation of the spatial distribution of these variables depends on the number and distribution of the observation stations. The spatial distribution of the average precipitation over a larger area including five watersheds is shown in figure 10(a, b) for all the 12 months of the year. The figures indicate that average monthly rainfall increases towards the south-western areas of the catchment. They further reveal that the catchment receives highest rainfall in March (86–142 mm) and lowest in November (18–32 mm). Analysis of the average yearly rainfall of 20 years also shows an increasing trend towards the south-western areas of the catchment. Southern areas receive 864–913 mm yearly average precipitation whereas north-western areas receive 423–472 mm. The southern areas are receiving higher precipitation because of the higher altitude. Most of the precipitation is in the form of snow in these mountainous regions of the catchment. As seen from the figures, there is marked spatial variation in the distribution of the precipitation for all months of the year. Further, orographic influences on precipitation are quite discernible from the interpolated precipitation patterns.

The analysis of 20 years (1979–1999) of meteorological data, as shown in table 2, indicates that the average daily maximum temperature was observed to be highest in July (29.59°C) and lowest in January (4.56°C) and average daily minimum temperature was observed to be lowest in January (−6.77°C) and highest in July (17.28°C). The average daily precipitation was observed to be maximum in March (4.38 mm) and minimum in November (0.59 mm). The average daily solar radiation was observed to be maximum in June (19.28 MJ/m²/day) and minimum in January (8.75 MJ/m²/day). The average daily dew point temperature was observed to be maximum in August (8.74°C) and minimum in January (−7.51°C). The average daily wind speed was observed to be maximum in April (3.4 m/s) and minimum in October (1.74 m/s). These values of the hydrometeorological parameters observed in the area are typical for temperate Himalayan regions.

4.4.2 Land use/land cover analysis

The various land use and land cover classes delineated in the five watersheds include exposed rocks, shrubs, forests, pastures and barren lands as shown

Figure 10. (a) Spatial distribution of average monthly rainfall of Rembiara catchment (January–June).

Figure 10. (b) Spatial distribution of average monthly rainfall of Rembiara catchment (July–December).

Figure 11. (a) Land use/land cover map and areal distribution of W1, W2 and W3.

in figure 11(a) for W1, W2 and W3, and figure 11(b) for W4 and W5. The distribution of the land use land cover classes in each of the five watersheds is given in table 8. W1 has 82.80%, 17.04% and 0.16% under exposed rocks, shrubs and pastures, respectively. W2 has 60.99%, 37.18% and 1.84% under exposed rocks, shrubs and pastures, respectively. W3 has 28.76%, 34.59% and 36.65% under barren lands, pastures and forests, respectively. W4 has 17.96%, 36.70% and 45.34% under barren lands, pastures and forests, respectively. W5 has

61.07%, 25.0%, 10.17% and 3.23% under exposed rocks, shrubs, forests and pastures, respectively. These results show that W1, W2, and W5 are mostly covered by exposed rocks while W3 and W4 have highest percentage of forest land. The type and distribution of land cover have profound impact on a number of hydrological processes (Matheussen *et al* 2000; Fohrer *et al* 2001; Quilbe *et al* 2008). Therefore, W1, W2 and W5 with lowest vegetation cover, shall generate more surface runoff compared to the other two watersheds. W5, in

Figure 11. (b) Land use/land cover map and areal distribution of W4 and W5.

Table 8. Land use/land cover distribution in the five watersheds.

Sl. no.	Land cover/ land use	Area (km ²)	% Area
W1 Watershed			
01	Exposed rocks	10.30	82.80
02	Shrubs	2.12	17.04
03	Pastures	0.02	0.16
W2 Watershed			
01	Exposed rocks	7.30	60.99
02	Shrubs	4.45	37.18
03	Pastures	0.22	1.84
W3 Watershed			
01	Barren land	3.06	28.76
02	Pastures	3.68	34.59
03	Forest	3.90	36.65
W4 Watershed			
01	Barren land	2.08	17.96
02	Pastures	4.25	36.70
03	Forest	5.25	45.34
W5 Watershed			
01	Exposed rocks	6.62	61.07
02	Shrubs	2.71	25.00
03	Forest	1.16	10.70
04	Pastures	0.35	3.23

particular, with highest drainage density and other geomorphological factors conducive for increased surface runoff, is prone to flooding during extreme storm events.

Table 9. Soil type distributions in the five watersheds.

Sl. no.	Soil type	Area (km ²)	% Area
W1 Watershed			
01	Rock outcrop	7.18	57.72
02	Sandy clay loam	5.26	42.28
W2 Watershed			
01	Rock outcrop	6.39	53.39
02	Sandy clay loam	5.58	46.61
W3 Watershed			
01	Clay loam	6.85	64.32
02	Sandy clay loam	3.79	35.68
W4 Watershed			
01	Clay loam	8.19	70.72
02	Sandy clay loam	3.39	29.28
W5 Watershed			
01	Rock outcrop	7.76	71.59
02	Sandy clay loam	3.08	28.41

4.4.3 Soil data analysis

The area under each of the soil texture types is given in table 9. It is evident that W1, W2 and W5 are dominated by rocky outcrops covering 57.72%, 53.39% and 71.59%, respectively. W3 and W4 are dominated by clay loam soils covering 64.32% and 70.72% of the total area, respectively. Sandy clay loam covers an area of 42.28%, 46.61%, 35.68%, 29.28% and 28.41% of W1, W2,

W3, W4 and W5, respectively. Soil texture properties such as the percentage of sand, silt, clay and soil hydrological groups of the watersheds are presented in table 10. Soil types influence the hydraulic properties of the soils and that in turn affect a number of hydrological processes at the watershed scale including the lateral and horizontal movements of the subsurface water (Entekhabi *et al* 1999; Romshoo 2004). Therefore, watersheds with large areas under barren and rocky outcrops

Figure 12. Simulated surface runoff of the five watersheds.

Table 10. *Soil hydrological groups in the five watersheds.*

Hydrological group	Sandy clay loam	Clay loam	Rock outcrop
	B	D	D
Sand (%)	62.95	34.35	–
Silt (%)	20.09	22.26	–
Clay (%)	16.96	43.39	–
Exposed rock	0.00	0.00	100.00

shall contribute pre-dominantly to runoff without much infiltration capacity. Similarly, the texture of the soil also determines to a large extent the moisture-holding capacity of the soils and to a great extent affects the infiltration and evaporation processes that inter alia affect the surface runoff and hydrographs of the watersheds (Tansey and Millington 2001). Therefore, W1, W2 and W5 will have higher surface runoff compared to the other two watersheds because of their varying soil characteristics.

4.4.4 Model simulations

Figure 12 shows the simulated runoff output from each of the five watersheds. The average annual runoff statistics of each watershed is given in table 11. As per the model simulation, W5 has the highest runoff of 11.17 mm/year followed by W1 (7.9 mm/year), W2 (6.6 mm/year), W4 (5.33 mm/year) and W3 (4.29 mm/year). These results indicate that W5 is more vulnerable to flooding during high rain spells followed by W1, W2, W4 and W3, respectively. The simulated results on the hydrological responses from the five watersheds are quite in agreement with those of the morphometric analysis. Instantaneous unit hydrographs of all five ungauged watersheds were developed, using the approach (Bhat 2009). From the analysis of the hydrographs, it is revealed that W5, with highest discharge potential and lower time to hydrograph peak, is more prone to flooding as compared to other watersheds. Results also reveal that W1 is the next vulnerable watershed due to large surges of water discharge and consequent flooding. Again, these results are in conformity with the hydrological simulation and the morphometric results discussed above. Therefore, it is quite evident that the geomorphological, physiographic characteristics and geological setting of

Table 11. *Predicted runoff as simulated by SWAT model.*

Watersheds	W1	W2	W3	W4	W5
Runoff mm/year	7.9	6.6	4.29	5.33	11.17

the watershed have significant impact on its hydrological response. Therefore, geomorphological studies are a pre-requisite for understanding the hydrological response of the watersheds and can be used to predict flood peaks, sediment yield and water discharge of ungauged watersheds (Chow 1964; Gardiner 1981; Al-Wagdany and Rao 1997).

5. Conclusions

Even though there is growing interest in research on natural disasters among geoscientists, there is still a significant gap in our understanding of the factors associated with flood hazard vulnerability (Beven 1989). This research study conducted in various representative sites is a step in that direction. It therefore addressed the fundamental research question of assessing the geomorphic and hydrological factors that make a drainage basin more or less prone to flooding. The three-pronged approach adopted in this study for characterizing the hydrological response of five watersheds with varied topography, land use/land cover, soils and geological setting indicates the strong relationship between the geomorphological, geological and hydrological setting of the watersheds. These research outcomes show that the geomorphometric characteristics at watershed scale have a strong influence on the hydrological characteristics and are direct and credible indicators to infer hydrological information including flooding and flood vulnerability of the ungauged watersheds (Patton 1988). However, these results need to be tested in other watersheds in the Jhelum basin in order to develop a simple model relating the geomorphology with the hydrology in the Jhelum basin to predict flood peaks, sediment yield and water discharge (Chow 1964; Gardiner 1981; Viera 2003). Such an operational model, when realized, shall go a long way in mitigating and developing an early warning system for flood management in the Jhelum basin.
