The chemical and isotopic compositions of thermal springs located along the Son–Narmada–Tapti (SONATA) mega lineament in central India have been investigated. The issuing temperatures of the thermal waters vary from 31° to 89°C for the thermal springs and 24° to 25°C for the cold springs. These thermal springs are located on the Archean Chotanagpur Gneissic Complex (CGC) in the eastern part of peninsular India. The thermal springs are mostly alkaline in nature with pH varying from 7.5 to 9.5. Piper diagram suggests that the chemistry of the thermal waters is compatible with the granitic host rocks through which the waters circulate. Mineral saturation index suggests that the thermal waters are saturated with cristobalite and quartz at lower temperatures (less than ~130 to 150°C), and calcite and forsterite at higher temperatures (~160° to 250°C). The estimated reservoir temperature based on chemical geothermometers is in the range of 132°–265°C, which favours a medium enthalpy geothermal system. Oxygen isotope fractionation of Bakreswar and Tantloi thermal springs highlights a higher reservoir temperature than estimated by chemical geothermometer. Positive gravity anomalies over Bakreswar and Tantloi areas strongly suggest a basement/mantle upliftment or mafic intrusion which could account for the heat source close to the surface. However, the large negative gravity anomaly depression around the Surajkund and Katkamsandi thermal springs indicates presence of deep seated faults.

1. Introduction

The states of Jharkhand and West Bengal host a number of thermal springs with issuing temperatures varying between 31° and 89°C. In West Bengal, these thermal springs occur at Bakreswar

(23°52'48"N; 87°22'40"E, Birbhum district) while in Jharkhand, they occur at Tantloi (24°2'8"N; 87°17'15"E, Dumka district), Surajkund (24°8'58"N; 85°38'43.14"E, Hazaribagh district), Katkamsandi (24°6'5.6"N; 85°12'7.57"E, Hazaribagh district) and Indrajurba (23°49'59"N; 85°30'E, Ramgarh district).

Keywords. Hazaribagh thermal spring; Bakreswar and Tantloi thermal spring; geochemistry of thermal water.

All these thermal springs issue through Chotanagpur Gneissic Complex (CGC) composed of calc-silicate, amphibolite, gabbro, pegmatite, and dolerite except the one at Indrajurba that flows through Gondwana sedimentary formations. The thermal springs at Tantloi with temperatures of 68°–70°C are located on ENE–WSW fault, while the Bakreswar thermal springs are located over NNW–SSE trending fault. The thermal springs at Surajkund lie over E–W trending fault (figure 1).

Deb and Mukherjee (1969), Bandyopadhyay and Nag (1989), and Majumdar *et al.* (2005, 2009) studied the chemical composition of Bakreswar and Tantloi thermal springs earlier. The geochemical signatures of the thermal springs show temporal variation with a few ions like Na, Cl, and SiO₂ recording major deviation. In the present paper, we report new chemical and isotope data on the above thermal springs and discuss the evolution of the thermal springs in the light of original gravity data and also point out the power generation capacity of this thermal province.

2. Geotectonic setting of the area

The Chotanagpur Gneissic Complex (CGC) of eastern peninsular India has undergone different tectonic activities from Precambrian onwards (Sarkar 1982) to Cenozoic Era (Dunn 1939, 1941; Ghosh 1948; Desikachar 1974; Shanker 1991). Deep circulation of meteoric waters in CGC along the fracture zones and ongoing tectonic movements resulted in several thermal manifestations over the period (Deb and Mukherjee 1969).

The basement rocks have four sets of vertical to subvertical joints trending NW–SE, NE–SW, ENE–WSW, and N–S (Nagar *et al.* 1996). A large number of dolerite dykes, trending parallel to the regional fractures, transect the granites (figure 1).

Tantloi thermal springs, controlled by a WNW–ESE trending fault, are situated 20 km NW of Bakreswar and issue through CGC, comprising charnockite and porphyritic granite gneiss. Gondwana formations that include Talchir shale (Pyrite content, Mukherjee 1964), boulder bed and gritty sandstone are also exposed north of Tantloi (Mukhopadhyay 1989; Mukhopadhyay and Sarolkar 2012) (figure 2). Other thermal springs at Surajkund, Katkamsandi, and Indrajurba are also located in the same geological setting.

3. Methodologies

Representative water samples were collected from the study area, comprising 15 thermal springs, one cold spring, and five groundwater samples. Two

Figure 2. General geology of (a) Bakreswar and (b) Tantloi study area with sample locations.

sets of water samples were collected. One set of water sample was acidified with HNO_3 on site and the other set was stored at a lower temperature for future analysis (Giggenbach and Goguel 1988). The pH and temperature measurements were determined in the field using ORION pH meter. Water samples were analyzed for major ion concentrations. Cations and silica were analyzed using ICP-AES. Sulphate concentration was measured with the aid of UV spectrophotometer; alkalinity was measured by H_2SO_4 titration, and chloride, by using ion selective electrode method (table 1). These analyses were carried out as per the standard procedures (APHA 1977). The analyses of oxygen and hydrogen stable isotopes were carried out at the Department of Earth Sciences, University of Florence, Italy.

4. Results and discussion

4.1 Hydrogeochemistry

Ground waters of the study area are near neutral to slightly alkaline ($\text{pH} = 6.9\text{--}7.8$ at 25°C) with dissolved solids varying from 367 to 612 mg/L. EC range from 548 to 913 $\mu\text{S}/\text{cm}$ and SiO_2 content in groundwater is 18–86 mg/L. The groundwater of the study area is of Na-HCO_3 type (table 1).

The thermal springs record wide range of surface temperatures varying from 31° to 89°C . They are near neutral to moderately alkaline ($\text{pH} = 7.5\text{--}9.5$ at 25°C) in nature with TDS varying from 461–924 mg/L (table 1). SiO_2 content is higher in thermal waters (97–143 mg/L) relative to groundwater (18–86 mg/L). Amongst the cations, Na is predominant (92–198 mg/L), while the concentration of K and Ca is low (<4 mg/L) except samples 8 to 12. Mg content (0.01–1.2 mg/L) is very less in the thermal springs.

All the water samples are plotted in the Piper diagram (Piper 1944) (figure 3). It is seen from figure 3 that the thermal springs are of Na-Cl type except for Indrajurba thermal spring of the Na-HCO_3 type. The cold spring (sample 16) shows typical groundwater character and is Ca-HCO_3 type.

4.2 Anion variation

Water samples from the study area were plotted in the $\text{Cl-SO}_4\text{-HCO}_3$ diagram (figure 4) to select suitable samples for estimation of reservoir temperature as suggested by Giggenbach (1988). As seen in figure 4, most of the thermal waters of the study area fall within the Cl field and samples 3, 4, 5, and 7 fall within the chloride/mature water field of Giggenbach (1988). These samples may be

be the result of reaction with pyrite bearing Gondwana sediments and Rajmahal volcanics that are exposed towards the northern part of the area of investigation (figure 1).

4.3 Geothermometry

Estimated reservoir temperatures based on silica concentration in thermal waters (Fournier 1973) and cation geothermometers are given in table 2.

Giggenbach (1988) proposed Na-K-√Mg ternary diagram for a more precise reservoir temperature

estimation. The reactions involving K-Na, equilibrate at high temperatures and do not adjust quickly to the physical environment at shallow depths, thus giving high values of reservoir temperature. While reactions involving K/√Mg, equilibrate at low temperatures and give very low reservoir temperatures. Giggenbach (1988) combined both Na-K and K/√Mg thermometers and gave Na-K-√Mg ternary diagram for estimating the reservoir temperatures. Thus for a more accurate estimation of the reservoir temperature, thermal waters of the study area were

Figure 5. Na–K– $\sqrt{\text{Mg}}$ geothermometer ternary diagram of Giggenbach (1988) showing the variation in study area thermal springs. The grey ellipse covers the plots of the previous work done by Majumdar *et al.* (2009).

plotted in the Na–K– $\sqrt{\text{Mg}}$ ternary diagram (figure 5).

Most of the thermal springs of the study area plot in the partial equilibrium field in figure 5. The estimated reservoir temperature for Bakreswar (samples 3–7) varies from 120° to 140°C while for Tantloi, the temperature is about 140°C. For the sake of comparison, the field of thermal springs reported earlier from Bakreswar and Tantloi (Majumdar *et al.* 2009) is also shown in figure 5. The estimated reservoir temperature for Surajkund varies from 160° to 190°C (samples 8–12, table 1) and is much higher compared to others. All other thermal springs plot in the immature field of figure 5.

4.4 Mineral equilibrium and geothermometry

Mineral equilibrium was calculated with the help of activity of the species in water samples over a range of temperatures. This is expressed for mineral k in terms of $\log (Q/K)_k$ (Reed and Spycher 1984):

$$\log \left(\frac{Q}{K} \right)_k = \log \prod_i a_{i,k}^{v_{i,k}} - \log K_k \quad (1)$$

where K is the equilibrium constant for mineral k , $a_{i,k}$ is the activity and $v_{i,k}$ is the stoichiometric coefficient of component species i in the

equilibrium mass action expression for mineral k , written with the mineral on the left-hand side. For supersaturated minerals, $\log (Q/K)_k$ value is greater than zero while it is less than zero for undersaturated minerals. Calculation of species in water samples were performed by PHREEQC (Parkhurst and Appelo 1999) with WATEQ4E thermodynamic database (Ball and Nordstrom 1991) included in the PHREEQC package.

The reservoir temperature of the study area calculated using Na–K–Ca geothermometer (Fournier and Truesdell 1973) is 120°C and 110°–190°C by the Na–K– $\sqrt{\text{Mg}}$ diagram (figure 5), while by Q/K plot (figure 6), the temperatures estimated are 130°–180°C. Figure 6 indicates that the geothermal water is in equilibrium with calcite and quartz, which may be a reflection of the fluids being derived from a much deeper source where the host rock is granite gneiss and later interacting with the enclaves of calc-silicate rocks at lower temperature at shallower depths. This accounts for the effects of different rates of re-equilibration of minerals with waters that are cooled during ascent (Reed and Spycher 1984).

4.5 Oxygen and hydrogen isotope

Groundwaters of the Bakreswar and Tantloi area vary in $\delta^{18}\text{O}$ values from -3.8 to -5.1‰ and δD

Figure 6. Mineral equilibrium diagram of (a) Surajkund, (b) Katkamsandi, (c) Tantloi, and (d) Bakreswar thermal springs of the study area.

value from -29.1 to -38.5‰ (table 1). Thermal waters of the area give $\delta^{18}\text{O}$ values in the range from -2.3 to -4.3‰ and δD values in the range of -33.1 to -24.1‰ . The oxygen and hydrogen isotopic compositions of the water samples were plotted in the $\delta^{18}\text{O}$ vs. δD diagram (figure 8). The position of the thermal waters with respect to the Indian meteoric water line (IMWL, IAEA 2008) shows 'oxygen shift' which signifies water-rock interactions above 220°C (Nutti 1991; Giggenbach and Soto 1992; Giggenbach 1992). Bakreswar thermal springs are clustered together except for Agnikund (sample #7) probably due to steam separation, resulting in oxygen and hydrogen shift (Truesdell *et al.* 1977; Giggenbach 1992). Groundwater samples of the study area also show oxygen shift as in figure 7, which strongly supports the thermal origin of the groundwater.

4.6 Gravity anomaly

Gravity anomaly map was prepared based on the terrain corrected Bouguer Gravity Anomaly map

of India (GSI 2006). The study area shown in figure 8 is characterized by high positive anomalies (30 mGal).

The gravity anomaly profiles were prepared along two E–W sections passing through Bakreswar and Tantloi thermal spring sites respectively, and also one NNW–SSE profile passing through both the thermal springs (figures 8, 9a). The E–W profile shows a large area of positive anomaly in Bakreswar and Tantloi geothermal fields. The profile from east to west over Bakreswar shows sudden change in gravity anomaly reaching up to 30 mGal, and then suddenly decreases to the negative anomaly. This behaviour of gravity anomaly occurs due to the presence of the fault in the area trending N–S (Telford *et al.* 1990; Jacoby and Smilde 2009). The profile NNW–SSE shows sudden change in the anomaly over Tantloi, possibly due to the presence of the ENE–WSW trending fault. It is interesting to note that these major faults are close to the hydrothermal manifestations. The gravity anomalies over these geothermal fields could be ascribed to a combination of hydrothermal metamorphism

Figure 7. Oxygen and hydrogen isotope variation diagram of Bakreswar and Tantloi water samples. Symbols are same as in figure 3 and the grey ellipse represents data from Majumdar *et al.* (2005).

Figure 8. Bouguer gravity anomaly map (terrain corrected) of the study area where S: Surajkund; K: Katkamshandi; I: Indrajurba; B: Bakreswar and T: Tantloi; F-F: SONATA mega lineament. Solid black lines indicate line along which Bouguer gravity anomaly profiles are constructed and are shown in figure 9(a and b).

of the sediments and concomitant local basement or mantle highs.

In the case of other geothermal sites, three gravity profiles were studied, two from Katkamsandi to Surajkund and Indrajurba and one from Surajkund

to Indrajurba (figure 8). Katkamsandi, Surajkund, and Indrajurba thermal springs fall in the negative gravity anomaly zone with Indrajurba thermal springs falling in the lowest negative anomaly zone (figure 9b). A sudden change in the gravity

Figure 9. Gravity anomaly profile around (a) Bakreswar and Tantloi geothermal field; (b) Surajkund, Katkamsandi and Indrajurba geothermal fields. Profile tracks are shown with solid black lines in figure 8.

anomaly near Indrajurba along the Surajkund–Indrajurba profile, may indicate a horst structure or a mafic intrusive facilitating propagation of thermal waters. Large variation in negative anomaly values between Surajkund, Katkamsandi, and Indrajurba can be related to deep seated faults in that area (ONGC (Oil and Natural Gas Commission) 1969). This geothermal province appears to be a part of the Son–Narmada–Tapi (SONATA) mega lineament, which runs parallel to the study area, and is most likely to rely on the source for the heat circulation in these thermal springs.

4.7 Spectral analysis of gravity anomaly

Energy spectrum analysis of gravity or magnetic anomaly has been widely studied by several researchers (Bhattacharyya 1966, 1978; Spector and Grant 1970; Gerard and Debeglia 1975) to decipher the subsurface structures. In addition to

the bouger gravity interpretation made and discussed in the above section, this method is applied for the present field site to bring out quantitative interpretation of the subsurface structure to render further support to the inferences made above. Thus the Bakreswar gravity anomaly profile (figure 10) suggests that the basement is located at a shallow depth of 0.6 km as shown in figure 10 as K1 and K2. The depth along the profile K2 is 1.5 km. Depth variation in both K1 and K2 sections is 0.7 km, which suggests faults below Bakreswar geothermal site.

5. Conclusions

Thermal springs of the study area belong to Na–Cl type except for two thermal springs that fall in the Na–HCO₃ field while the cold spring is of Ca–HCO₃ (figure 3). The groundwater, on the other

Figure 10. Gravity anomaly along the Bakreswar geothermal site, K1 and K2 is the length taken for spectral analysis to estimate the depth to anomalous sources.

hand, defines an array between the cold spring and the thermal spring indicating a large thermal spring component in the ground water. This is very well seen in the oxygen–hydrogen isotope diagram of Bakreswar and Tantloi geothermal field (figure 7) where the groundwater exhibits a large oxygen shift. The temperature estimated using the cation geothermometers yields a temperature much higher than reported in earlier studies (Majumdar *et al.* 2005, 2009). It is apparent that the ascending waters are reacting with the wall rock at temperatures greater than 220°C. One of the thermal springs (sample 7) also shows a hydrogen shift indicating steam loss during its ascent (Nuti 1991; Giggenbach and Soto 1992; Giggenbach 1992, figure 7).

The presence of high He content (1.5%) and low Kr/Xe ratio (0.262) in thermal gases from Bakreswar and Tantloi (Ghose and Chatterjee 1980; Ghose *et al.* 1989) suggests that the thermal springs are ascending through high heat generating

granites. This is further supported by high heat flow values reported (200 mW/m², Shanker 1988; Chandrasekharam 2000) in this area. The environment through which the above thermal springs are circulating appears to be similar to Tattapani thermal province in Chhattisgarh where the thermal gases contain high He content (1.54%, Minissale *et al.* 2000) with high heat flow value (280 mW/m², Chandrasekharam and Chandrasekhar 2010). Both deep seated fault system (SONATA) and high heat-generating granites appear to be the main factors for circulating the thermal springs of this area.

In case of Surajkund, Katkamsandi, and Indrajurba thermal springs, the plots (figure 3) although similar to Bakreswar and Tantloi thermal springs, the Surajkund thermal spring registered higher reservoir temperature (190°C, figure 5) compared to other thermal springs. As reported above, the influence of pyrite present in the Talchir shales and Rajmahal Traps is very well reflected in the shift of the plots towards the sulphate fields as in figure 3.

The gravity anomaly pattern gives indication of mantle upwarp in this region supported by the presence 100–105 Ma (McDougall and McElhinny 1970) Rajmahal Traps in north of Tantloi. Thus, the geothermal system in the Bakreswar–Tantloi area is controlled by both deep seated structures and high heat-generating host granites. It has to be seen further whether any mantle He is present in the thermal gases to understand the involvement of mantle in the evolution of the thermal springs in this area. Considering the reservoir temperatures indicated by the isotope signatures, emanation of high He content in the thermal gases and gravity anomaly pattern over the Bakreswar and Tantloi thermal sites, we find that these sites are potential areas for geothermal development as well as extraction of He from the thermal gases for commercial purposes. Pilot plants to extract and purify He from the thermal gases of Bakreswar and Tantloi are already in operation (Ghose and Chatterjee 1980; Ghose *et al.* 1989). Exploratory drilling for He extraction on a commercial scale combined with installation of 5 MWe binary power plant in Bakreswar and Tantloi sites are being undertaken based on hydrogeochemical and geophysical characteristics of the geothermal fields investigated by various works in the study area.

Acknowledgements

Authors are thankful to Prof. S Viswanathan for his valuable suggestions during the initial stages of the preparation of the manuscript. The authors extend their appreciation to the Deanship of Scientific Research at King Saud University through the research group project No. RGP VPP-122. They thank Prof. M Radhakrishna for rendering help in spectral gravity interpretation. Authors also thank the anonymous reviewer for the valuable suggestions, which improved the quality of the paper.
