The Giouchtas Mountain is situated south of Heraklion, Central Crete. It is a N–S trending morphological asymmetric ridge with a steep western slope, whilst its eastern slope is characterized by a smoother relief, composed of Mesozoic limestone and Eocene–lower Oligocene flysch of the Gavrovo–Tripolis zone. The present study focusses on the structural pattern and development of Giouchtas Mountain. Morphotectonic analyses in combination with field mapping and tectonic analysis were performed for this purpose. GIS techniques were used for mapping the spatial distribution of the geological features on the topographic relief of the area. Geomorphic indices, used in the present study, are the mountain front sinuosity index (Smf) and the valley floor/width ratio index (Vf). Based on Smf and Vf values, it is implied that this area can be assigned to a tectonic class I, corresponding to higher tectonic activity. However, spatial variations of the tectonic activity along the segmented fronts point to a general trend of increasing activity towards the north and especially, northeast. The model of this possibly active structural feature corresponds to a compressional mechanism followed by an earliest Mid. Miocene to Holocene late-stage deformation related to extensional faulting.

1. Introduction

Crete is situated in the outer-arc region of the Aegean–African subduction system. Recording N–S and E–W stretching forms a complex mosaic of tilt blocks and associated late Miocene and younger sedimentary basins (Meulenkamp *et al.* 1988; van Hinsbergen and Meulenkamp 2006; Kokinou and Kamberis 2009; Kokinou *et al.* 2012). The topography of Crete is therefore characterized by a highly mountainous landscape, suggesting rather young and rapid uplift (Pirazzoli *et al.* 1982, 1996;

Stiros 1996; Roberts *et al.* 2013; Gallen *et al.* 2014). A fast rise of the island is also indicated by Neogene marine deposits of middle Miocene to early late Pliocene age that have been uplifted up to several hundreds of meters above the present sea level (Meulenkamp *et al.* 1988, 1994). A large number of surface faults underline the essential input of intense tectonic activity on both the surface itself and the landscape evolution (Bonnefont 1977; Angelier 1979).

The Heraklion basin, where the study area is located, comprises a 900 km² Neogene basin

Keywords. Geomorphic indices; middle Miocene; compression tectonics; Late Neogene–Quaternary; extensional faulting.

bounded to the east by Dikti Mountain, to the west by Psiloritis Mountains and to the south by Asteroussia Mountains. The Neogene deposits of Heraklion basin overlie the basement rocks of the Upper Nappes (Gavrovo–Tripolis, Pindos, and the heterogeneous Uppermost Unit). The Upper Nappes in the Psiloritis and Dikti Mountains are separated from the HP–LT metamorphic rocks of the lower Nappes (parautochthone Plattenkalk and Phyllite-Quartzite units) by the Cretan detachment (Jolivet *et al.* 1996; Ring *et al.* 2001; Ring and Reischmann 2002; van Hinsbergen and Meulenkamp 2006; Zachariasse *et al.* 2011). This detachment, in many places, is exposed with a sense of shear either to both south and north (Kilias *et al.* 1994; Fassoulas 1999), or dominantly top to the north (Jolivet *et al.* 1996). Recent kinematic and structural studies (Chatzaras *et al.* 2006; Craddock *et al.* 2009; Tortorici *et al.* 2010) emphasize the important role of the compression (also supported by the present work) in the exhumation mechanism of the high-pressure rocks exposed on the island of Crete.

The evolution of a landscape is the result of complex interactions involving climate, tectonic and surface progress (Burbank and Anderson 2001). Therefore, the study of the geomorphology assist in understanding the landscape evolution (e.g., Bathrellos *et al.* 2009a; Migiros *et al.* 2011; Kamberis *et al.* 2012) and to estimate the geomorphologic hazard (Skilodimou *et al.* 2003; Bathrellos *et al.* 2009b, 2012, 2013; Rozos *et al.* 2011, 2013; Panagopoulos *et al.* 2012; Papadopoulou-Vrynioti *et al.* 2013). Moreover, in active tectonic regions geomorphic features is an essential tool to recognize active movements, assisting the studies of the tectonic geomorphology (Keller and Pinter 1996; Azor *et al.* 2002). Several studies have proposed that the investigation of the geomorphic features and geomorphic indices such as the mountain front sinuosity (Smf index) and the valley floor width to valley height ratio (Vf index) provide useful information regarding the influence of tectonics on landscape evolution (e.g., Bull and McFadden 1977; Rockwell *et al.* 1984; Keller 1986; Keller and Pinter 1996; Burbank and Anderson 2001; Cuong and Zuchiewicz 2001; Theocharis and Fountoulis 2002; Silva *et al.* 2003; Al-Taj *et al.* 2007; Tsodoulos *et al.* 2008; Dehbozorgi *et al.* 2010).

The present work aims at a better understanding of the complex geological conditions and the structural pattern in the mountainous area of Giouchtas (figure 1a) located in the Archanes municipality in central Crete. Specifically, the present work describes the development of a tectonic structure from the Eocene–early Oligocene up to recent times. For this purpose, a morphotectonic analysis in combination with detailed geological and

tectonic survey was conducted. Field measurements of outcropping faults, such as fault strikes, fault dips, and slickenside lineations, comprise the most accurate data on fault geometry and reconstruct the structural development of the study area. A 1:5000 digital terrain model, structural, and stratigraphic data were combined in a GIS database. This database enabled not only the easy visualization of the results but also contributed to spatial analyses and correlations among the various geological features.

2. The study area

The dominant morphological feature of the study area is the Giouchtas Mountain (Mt.), which presents an elongated shape (figure 1b). It extends N–S, roughly 5.3 km long with a maximum altitude reaching 811 m.a.s.l. This mountain presents steep slopes, often interrupted by narrow valleys and it is surrounded mainly by a hilly area where the maximum elevation is 485.10 m.a.s.l. The western flank of Giouchtas Mt. has slopes greater than 60°, while the eastern one is greater than 50° (figure 1c). As shown later in the present study, the Giouchtas Mt. comprises an asymmetric thrust fault related anticline affected by a late-stage, early late Miocene to Holocene, intense extensional deformation. The narrow plain of Archanes is located east of the mountain.

Giouchtas Mt. is surrounded by streams. The drainage network, developed mostly to the north and to the east of the mountainous area, acquires the largest extension within the study area (figure 1b, c). The Knossanos River stream drains the northern and eastern flanks of the mountain as well as the plain of Archanes. This stream flows to the north, running through Knossos, and reaches the Aegean Sea. Part of this stream runs through a deep canyon with steep slopes in the northeast piedmont of Giouchtas Mt. creating a narrow V-shaped valley (figure 1b, c, northeast of Giouchtas Mt.). The drainage network presents a rather parallel pattern. The western flank of Giouchtas Mt. is drained by streams, forming the upper part of Gioufyros River, which also discharges to the Aegean Sea. The flow of the stream shows a dominant NW–SE and E–W trends.

The study area (figures 1b and 2a–l) belongs to the Gavrovo–Tripolis zone. According to Brünn (1956) and Aubouin (1959), the external Hellenides in western Greece (Pindos, Gavrovo–Tripolis, Ionian and pre-Apulian zones), consists of a series of sub-parallel, north–south trending tectonostratigraphic zones including several east-dipping thrust sheets and west verging folds. The Gavrovo–Tripolis zone represents a stable shallow carbonate dominated

Figure 1. (a) Location of the study area; (b) topographic relief showing the wide area of study with the main structural features; and (c): morphological features of the study area produced from 4 m digital elevation data.

platform (Dercourt 1964). The Gavrovo–Tripolis sediments include middle Triassic to upper Eocene limestones and Eocene to lower Oligocene flysch (Fleury 1980). The permanent shallow-water sediments of late Jurassic to latest Cretaceous, appear as a distinct unit affected by successive regressive episodes (Bernier and Fleury 1980). According to Alexander *et al.* (1990), this unit structurally underlies Pindos thrust sheets. The recent work of Chatzaras *et al.* (2013) and previous research in Crete (Chatzaras *et al.* 2006; Tortorici *et al.* 2010) support the presence of a crustal scale oblique ramp

(formed above an inherited Mesozoic fault zone) in the external Hellenides thrust belt on Crete.

The carbonate sequences (figures 2a–f, i, 3) exposed in Giouchtas Mt., located in the northern and southern parts of the mountain, comprise Jurassic–lower Cretaceous (J–K) light grey to grey black, medium bedded to massive, karstic, limestones. Dolomitization decreases from base to top. The central part of Giouchtas Mt. is dominated by upper Cretaceous (Ks.k), grey–black medium-thick bedded, bituminous and dolomitic limestones. Flysch (figures 2h, 3) of upper Eocene–Oligocene age,

Figure 2. Photos from the study area showing the tectonostratigraphy: (a) view to the west, a carbonate hill surrounded by Miocene sediments is recognised, (b) view to the west, normal fault in the carbonate sequence, (c) location to the west, Jurassic-lower Cretaceous limestones, (d) location to the south, normal fault in Jurassic-lower Cretaceous limestones, (e) location to the west, upper Cretaceous limestones, (f) location to the east, normal fault in upper Cretaceous limestones, (g) location to the west, coarse-grained coherent Quaternary sediments, (h) location to the east, flysch of upper Eocene-Oligocene, (i) location to the east, contact of Jurassic-lower Cretaceous limestones and upper Cretaceous limestones, (j) location to the west, Miocene formations, (k) and (l) location to the east, Miocene formations.

belonging to the Gavrovo-Tripolis zone, is detected in the north-eastern flank of the mountain, comprising alterations of schists and sandstones with small layers of grey calcareous turbidites.

Miocene sediments (M) around Giouchtas Mt. shown in figures 2j, 2l and 3, consist of: (a) middle

Miocene fluvial-lacustrine clays (Mm) with local lignite, limestones and sandstones, (b) upper Serravallian marine clays and silty clays with intercalations of sandstones (M.l.st), (c) middle-upper Miocene breccias and breccio-conglomerates (M.pt), (d) Tortonian marine and fluvial conglomerates

Figure 3. Geological map of the study area, the major mountain fronts, and locations commented in the text. Morphometric data were collected along fronts shown in this figure.

(Mc), sandstones, siltstones, marls, clays, and lignites, (e) upper Miocene bioclastic limestones (Mk) and gypsums (g). The Pliocene sediments (Plm) consist of marls or marly limestones, clays with marls, lamellar marls or diatomites and bioclastic limestones.

Moreover, coarse-grained coherent and loose Quaternary sediments (figure 2g) were observed in several locations of the study area during the fieldwork. Alluvial deposits (al), consisting of loose

clay-sandy materials and 'terra rossa', are also present.

3. Methodology

3.1 Geographic Information System (GIS)

Digitization techniques and GIS were applied for mapping representation of the data. The digital

elevation model was created by the digitization of the topographic map contours (1:5000 scale maps), while the cell size of the digital elevation model was 4 m. A spatial database was created, and ArcGIS 9.3 software was used to process the collected data. This study was carried out using topographic maps (3 sheets) of a scale of 1:5000, published by the Hellenic Army Geographical Service (H.A.G.S.). A Digital Elevation Model (DEM) was created by digitizing the contours with 4 m intervals and trigonometric points of the above-mentioned topographic maps. The slope map was derived from the DEM and the slopes were grouped in eight classes: (i) 0–10°, (ii) 11–20°, (iii) 21–30°, (iv) 31–40°, (v) 41–50°, (vi) 51–60°, (vii) 61–70°, (viii) >70° (figure 1c). The geological map of the study area was created, based on the existing geological map (IGME, 1:50,000) and field observations.

3.2 Geomorphic indices

Geomorphic indices are useful tools in evaluating the tectonic activity (Turowski *et al.* 2006, 2009; Brocklehurst 2010), relating the sensitivity to rock resistance, climatic change, and tectonic processes with the production of a certain landscape. The most useful indices are the mountain front sinuosity (Smf index, Bull and McFadden 1977) and the valley floor width to valley height ratio (Vf index; Bull 1977, 1978).

Mountain front sinuosity is determined by measuring the length of the mountain front along the foot of the mountain Lmf and the straight line length of the mountain Ls ($Smf = Lmf/Ls$) (Bull and McFadden 1977). This index reflects the balance between erosion that tends to produce irregular or sinuous fronts and tectonic forces that tend to create a straight mountain front coincident with an active range-bounding fault. Values of Smf approach 1.0 on the most tectonically active fronts, whereas Smf increases if the rate of uplift is reduced and erosional processes begin to form a front that becomes more irregular with time. Smf values lower than 1.4 indicate tectonically active fronts (Rockwell *et al.* 1984; Keller 1986; Burbank and Anderson 2001), while higher Smf values (>3) are normally associated with inactive fronts in which the initial range-front fault may be more than 1 km away from the present erosional front (Bull and McFadden 1977).

In this study, the examined fronts were separated in six discrete segments, corresponding to the directions of the major faults present in the study area and they are illustrated in figure 3 by a red line. The fronts (1) and (3) are parallel to the faults trending NNE–SSW at the eastern and western sides of Giouchtas Mt. The

fronts (2) and (4) are also parallel to the NW–SE trending faults, located at the north-eastern and south-western side of Giouchtas Mt. The front (5) crosses the Giouchtas Mt. corresponding to the general direction of the WNW–ESE trending faults. Finally, the front (6) was examined separately because a group of NE–SW trending faults was present in the northeastern proximity of Giouchtas Mt. Moreover, the selection of the fronts was based on similar geological and morphological criteria such as: (a) intersection with large in scale cross-cutting drainage, relative to the front, (b) abrupt changes in lithology (e.g., formation prone to erosion progress, (c) changes in mountain front orientation (Wells *et al.* 1988). The reported Sm data are the mean values of each front, since five different Lm values were calculated to measure the mean Sm value (Silva *et al.* 2003).

The Vf index reflects the difference between V-shaped valleys that are down-cut in response to active uplift (low values of Vf) and broad-floored valleys that are eroding laterally into adjacent hill slopes in response to base level stability (high values of Vf) (Bull 1978). The ratio of valley floor width to valley height (Vf) may be expressed as:

$$Vf = 2Vfw / ((Eld - Esc) + (Erd - Esc)),$$

where Vfw is the width of valley floor, Eld and Erd are elevations of the left and right valley divides, respectively, and Esc is the elevation of the valley floor (Bull and McFadden 1977). The comparison of the floor width in a valley with its mean height provides an index that indicates whether the stream is actively down-cutting or is primarily eroding laterally into the adjacent hill-slopes. In this way, the index reflects differences between broad-floored canyons (U-shaped) with relatively high values of Vf and V-shaped canyons with relatively lower values (Keller 1986). The Vf index is often measured for the most important valleys along the examined mountain fronts (Bull and McFadden 1977; Azor *et al.* 2002; Silva *et al.* 2003). In the present study, Vf index was determined in the valleys of each mountain front. Vf values were calculated in different segments at distances of 20 m along the stream length with similar geological and morphological characteristics (Verrios *et al.* 2004). The Vf values of different segments were further statistically processed to specify the mean Vf value and the standard error was also measured.

3.3 Tectonostratigraphic analysis

Field work and consequent analysis were carried out applying well tried techniques (e.g., Mercier 1976; Hancock 1985). Data were collected in restricted sites, according to stratigraphic units, to

facilitate the chronological distinction between the different tectonic phases and firstly correlated with the geological map of Greece (1:50,000), Epano Archanes Sheet and Heraklion Sheet (IGME). When two generations of faulting were present in the same site, they were divided before any numerical analysis. The separation is necessary because the two fault systems are often not mechanically compatible. This procedure was carried out using (a) the simple criterion of relative overprinting between two generations of striations (e.g., Mercier *et al.* 1989), (b) geometric and morphotectonic elements such as the strike, dip and plane of the faults, the presence of recent screes, facets and fault scarps, (c) the relative dating of the hydrographic network streams, since the low order streams are younger than the high ones (e.g., Kamberis *et al.* 2012).

The structural analysis of each site has been done as follows: first, the graphical approach of the directional histogram for planes was an important check on the mechanical compatibility between families of faults. The angle of deviation in all cases was $<15^\circ$. The former analysis was mainly applied using the right dihedral method and circumstantially the P and T axes. Both analyses not only give the three principal axes of the stress field, but also some index, such as the mean standard deviation or angular deviation, which indicates the reliability of the result itself. Tectonic analysis has been done using FP tectonics.

Miocene and Pliocene sediments have been dated by planktonic foraminifera biostratigraphy. 22 samples were collected from the formations near the fronts (figure 3). Biostratigraphic analysis was based on the qualitative analysis of planktonic foraminifera.

4. Results and analysis

4.1 Stratigraphic data

The fronts (1) and (2) are located in the eastern flank of the Giouchtas Mt. The front (1) consists of Jurassic–lower Cretaceous limestones, upper Cretaceous dolomitic limestones, upper Eocene–Oligocene flysch (geological map of Greece (1:50,000, Epano Archanes Sheet)) and upper Tortonian–Messinian bioclastic limestones. The age of the last sediments is indicated by the presence of *Globorotalia miotumida* (figure 4a), *Globigerinoides obliquus* and *Neogloboquadrina acostaensis*, belonging to Biozone 11 of Zachariasse *et al.* (2011). The microfauna assemblage also contains specimens belonging to *Bolboforma* group, *B. intermedia* and *B. clodiusi* (figure 4d) supporting

an upper Miocene age (Antonarakou and Drinia 2004; Drinia and Antonarakou 2012).

The front (2) consists of Jurassic–lower Cretaceous limestones, upper Eocene–Oligocene flysch as well as Miocene sediments (geological map of Greece (1:50,000, Epano Archanes Sheet)). The Miocene exposure contains fluvial-lacustrine clays of middle Miocene age and Tortonian marine and fluvial conglomerates, which contains planktonic and benthic foraminifera and ostracodes assigned to an inner neritic environment. Pliocene marine sediments are defined by the presence of *Globigerinoides ruber* and *Sphaeroidinellopsis seminulina* (figure 4b and c), (Drinia *et al.* 2008). These sediments were previously reported (geological map of Greece (1:50,000, Epano Archanes Sheet)) as middle Miocene fluvial and lacustrine clays.

The fronts (3) and (4) are located in the western flank of the Giouchtas Mt. The front (3) crosses Jurassic–lower Cretaceous limestones, upper Cretaceous dolomitic limestones, and middle Miocene fluvial-lacustrine clays, as well as upper Miocene bioclastic limestones. The outcropping rocks along the front (4) are: Jurassic–lower Cretaceous limestones, and middle Miocene fluvial-lacustrine clays (geological map of Greece (1:50,000, Epano Archanes Sheet)).

The front (5) is oriented almost transverse to the development axis of Giouchtas Mt. Along this segment, upper Cretaceous dolomitic limestones, upper Eocene–Oligocene flysch and Miocene sediments (middle Miocene fluvial-lacustrine clays, Tortonian marine and fluvial conglomerates, and upper Miocene bioclastic limestones) are observed.

The front (6) is located in the NW edge of the Archanes plain and it is about 3.4 km long. Upper Miocene bioclastic limestones and Pliocene marls, marly, and bioclastic limestones outcrop along this front.

4.2 Morphometric analysis

The location, bounding rocks, trend, length, and the values of the morphometric indices, are presented in table 1. The front (1) has a length of 4.8 km long and corresponds to a large fault trending $N20^\circ\text{--}25^\circ\text{E}$ and the mean value of the Smf index is 1.11. The Vf values range from 1.21 to 0.052, while the mean value is 0.43 ± 0.21 . The front (2) is 1.5 km long and borders another fault trending $N157^\circ\text{E}$, the Sm mean value is 1.09, while Vf values vary from 0.24 to 0.22 and the mean value is 0.23 ± 0.015 , lower compared to the Vf of the front (1).

The fronts (3) and (4) correspond to lengths of 5.5 and 2.7 km, respectively. These are situated near the faults trending $N15^\circ\text{--}20^\circ\text{S}$ and $N140^\circ\text{E}$

Figure 4. Planktonic foraminifera species from the Neogene sediments east of Giouchtas Mt. (a) *Globorotalia miotumida*, (b) *Globigerinoides ruber*, (c) *Sphaeroidenellopsis seminulina*, and (d) *Bolboforma clodiusi*.

respectively. The mean value of the Smf is 1.13 for the front (3) and 1.27 for the front (4). The Vf values range from 1.67 to 0.37 and the mean value is 0.876 ± 0.14 for the front (3). The front (4) has values of Vf varying from 1.21 to 0.32, while the mean value is 0.7 ± 0.18 . The mean values of both geomorphic indicators in the west side of Giouchtas Mt. are lower than the eastern ones.

The front (5) is approximately parallel to the border fault zone trending almost $N \sim 112^\circ E$. The length of this segment is 4.5 km and the Smf index values decrease from the eastern (2.42) to the western (1.2) flank of Giouchtas Mt. The mean value of Vf is 0.74 ± 0.17 .

The front (6) is about 3.4 km long and the value of the Smf is 1.1. The Vf values range from 1.9 to 0.21, while the mean value is 0.73 ± 0.15 .

In conclusion, the Sm and Vf values corresponding to the fronts (1) and (2) are lower compared to the values of the fronts (3) and (4), but generally greater activity for the northern part of Giouchtas Mt. is recommended. It should be mentioned that the canyon, located east of the front (2), was probably created due to the tectonic activity related to front (2). The stream, running through this canyon, was probably flowing N–E in the past, crossing the plain of Archanes (figure 1c). Due to later faulting in the study area, the stream flowing to the north was rapidly eroded headward along the clastic Miocene deposits. By headward erosion, the stream captured the north-eastward flowing drainage network and led to drainage piracy.

The front (5), striking approximately ESE–WNW, presents higher Sm values (2.42) east of

Table 1. Values of geomorphological indices for the fronts (1–6) shown in figure 3.

Front	Location	Bounding rocks	Front trend	Front length (km)	S _{Mf}	V _f		
						Max	Min	Mean, St. er.
1	Eastern flank	J-K, Ks.K, Ft	N20°–25°E	4.8	1.11	1.21	0.052	0.43±0.21
2	Eastern flank	J-K, M	N23°W	1.5	1.09	0.24	0.22	0.23±0.015
3	Western flank	J-K, Ks.K, M	N15°–20°E	5.5	1.13	1.67	0.37	0.87±0.14
4	Western flank	J-K, M	N23°W	2.7	1.27	1.21	0.32	0.7±0.18
5	From the eastern to the western flank	Ks.K, Ft, M	N67°–68°W	4.5	2.42–1.2 (from east to west)	1.72	0.31	0.74±0.17
6	NE from the eastern flank	M, Pl.m	N45°E	3.4	1.1	1.9	0.21	0.73±0.15

Giouchtas Mt. – Archanes plain – compared to the values (1.2) west of Giouchtas Mt., corresponding to greater activity for the western part of Giouchtas Mt. However, the V_f values for this front are low, possibly related to the recent extensional field affecting the area. Although the exposed Miocene sediments along the front (6) show low resistance to the erosion progresses, the S_m values for this front are low (1.1). Similarly, the V_f value is low suggesting high tectonic activity of the NE trending fault system, located NW of the Archanes plain.

4.3 Structural data and classification

Cross-cutting relationships between the members of the different fault systems, morphotectonic features and overprinting criteria were used in order to classify, both compressional and extensional structures (Kokinou *et al.* 2010) and related stress field patterns.

4.3.1 Compressional tectonics

According to Angelier (1979), reverse and strike slip faults on Crete are rare, small and caused by brief compressional events. Moreover, the overall S-directed thrusting that occurred during the Miocene and the earlier contractional events (figure 6), was accompanied by minor back-thrusting. It was associated with both reactivation of pre-existing structures and creations of new ones. However, recent studies on the island of Crete (Chatzaras *et al.* 2006; Tortorici *et al.* 2010; Chatzaras *et al.* 2013) propose that the evolution of windows in central Crete was controlled by two main contractional phases of deformation. The first contractional phase is related to NNW–SSE compression resulting in nappe stacking via low-angle thrusting. The second contractional phase was governed by NNE–SSW compression and involved conspicuous thrust-related folding, considerable tectonic imbrication and formation of a middle Miocene basin.

In the study area, the contractional structures, which are bounding the western flank of Giouchtas Mt. (figure 5b), witness contraction-related movements that probably acted in the Eocene–Oligocene and in the middle Miocene times (figure 6). These NW–SE and NE–SW trending movements, respectively, resulted in the formation of an asymmetric anticline, the Giouchtas Mt., which might be related at their latest stage to the ENE–WNW contraction tectonics firstly inferred by Benda *et al.* (1974) and Meulenkamp (1979) for the eastern Mediterranean and Crete. Moreover, a compressional structure recorded in the Jurassic–

Figure 5. Reverse (a, b) and normal (c, d, e, f) faults in the study area. Direction of slip is indicated by the red arrow.

late Cretaceous rocks presents the NE–SW trending general strike of the Alpine deformation (southeastern flank of Giouchtas Mt., figures 3, 5a, 6). Finally the presence of possible strike-slip fault next to the back-thrust (figures 5a, 6) may be a significant structural element of the exhumation related mechanism (Chatzaras *et al.* 2006) for the Giouchtas Mt.

4.3.2 Extensional tectonics

Normal fault systems are indicated in Giouchtas Mt., i.e., late Serravallian, latest Serravallian (?)

to early Tortonian, early to middle Tortonian, late Tortonian, early Pleistocene and finally middle Pleistocene to recent times, depicting the above-mentioned tectonic episodes. The results of the fault plain analysis, the fault strike classification and the correlation to similar studies in the central and eastern Crete, are shown in detail in figure 6.

First fault system (E–W). The first group includes, roughly E–W trending, in the order km-scale faults (figure 3) active until late Serravallian times. Angelier (1979) supported that large normal block faulting probably occurred in Serravallian

Figure 6. (a) Schmidt projections of the dominant faults (extensional, compressional and possible strike slip) and slip vectors on them resulting from the fault plane analysis. Sites of measurements are indicated by Gni (normal), Gri (reverse), Gsti (strike-slip), where $i=1,2,\dots$ (b) Fault classification in Giouchtas Mt. (1) and comparison to other studies (2) Central Crete: B = Benda *et al.* (1974); A = Angelier (1979); Me = Meulenkamp (1979); M = Mercier (1981); Mercier *et al.* (1989); L-Ca = Lyon-Caen *et al.* (1988); Fr = Frydas (1998); Fa = Fassoulas (2001); (3) Central/Eastern Crete (ten Veen and Postma 1999).

times. Fault surfaces and kinematical indicators of these faults are not well preserved. However, overprinting relationships (based on fault intersections and stratigraphic boundaries) indicate that it might correspond to the group A (figure 6,

column 3) determined in the central and the eastern parts of Crete by Benda *et al.* (1974), Meulenkamp (1979), Frydas (1998), ten Veen and Postma (1999). Few, E-W general trending, members of this group (figures 3, 6) seem to be intersected

by the Giouchtas Mt. Ridge, supporting that they probably acted in earlier times than the contraction-related movements referred by Benda *et al.* (1974) and the present study.

Second fault system (N120E–N140E). The second group, belonging to the N120E (to N140E) trending, presents high angle surfaces and normal dip slip component. These faults mainly cut the older, pre-neogene and neogene rocks (Location 1 in figures 3, 5c). However, tectonic movements on some fault surfaces may indicate that the corresponding episode started earlier, probably at the latest Serravallian times. All these faults are intersected by N20–28E fault (figure 3, Locations 2, 3, 4) observed in abundance (ten Veen and Postma 1999) in central Crete at the eastern side of Ida Mountains. Tectonic status at the location (1) corresponds to N222° extension which is similar to the earliest Tortonian episode referred by ten Veen and Postma (1999).

Third and fourth fault systems (N00E–N020E and N030–40E). The third and the fourth groups belong to the N00E–N020E and to the N030–40E trending faults, respectively. Both groups show generally high angle surfaces (70°–80°), except a small number of faults belonging to fourth group that show medium (50°–60°) and normal dip slip component. The differentiation between the two groups is mainly based on the stress field ($\sigma_3 = 97^\circ$ to 123°). These members deformed the older generations of faults (Locations 1, 5, 6 in figures 3 and 5d) and are mainly related to the middle and the late Tortonian tectonic activity. At this point, we have to refer that strike slip motion (figure 6) has also been indicated in two members of the third group. Similar strike slip motion has been reported by ten Veen and Postma (1999) in the same period. These authors referred that the late Tortonian to early Messinian episode is marked by important tectonics, related to the beginning of N075E-orientated oblique slip. Faults, belonging to the N020E trending system, bound the Giouchtas Mt. (Locations 5, 6 in figure 3) as it is also inferred by Fassoulas (2001). At location (4), N10–20E fault post-dates the older N110–112E trending structure, while it is cut by a N160–165E fault (Location 7 in figure 3). It is also noteworthy, that ten Veen and Postma (1999) referred the strong vertical fault movement along N020E, including the Sitia Fault Zone, Ierapetra Fault Zone (Gaki-Papanastassiou *et al.* 2009; Alves and Lourenço 2010) and the W Dikti Fault Zone.

The reactivation of normal faulting along the older, roughly E–W trending, extensional structures, during early Messinian, characterized by a

roughly dip slip component (close to the locations 1 and 8 in figure 3) is also supported by this work.

Fifth fault system (N040E–N060E). The fifth group of extensional structures includes the N040E to N060E trending faults showing high angle surfaces and normal dip slip component (Locations 3, 9 in figure 3). These are moderate-scale NE–SW striking faults (figure 6, column 3) associated with the Pleistocene to recent times tectonic activity. At the location (9) in figure 3, N050E trending faults formed a small graben. However, the dextral lateral motion, referred by ten Veen and Postma (1999) for similar structures in the central and the eastern Crete, is not observed in this area.

Sixth fault system (N160E–N180E). The sixth group includes the youngest members, belonging to the N160E–N180E trending faults (Locations 3, 4, 5, 10, 11, 12 in figure 3 and in figure 5e, f). They present high angle surfaces and normal dip slip component, too. Especially, at locations (3) and (13), part of the flysch is trapped between two similar faults with significant vertical throw. Faults belonging to the N160E group intersect all the above-mentioned faults and are probably associated to the radial extension dominating in the southern Aegean area (Angelier *et al.* 1982). This group is also indicated in adjacent areas covered by Holocene sediments. Armijo *et al.* (1982) and Lyon-Caen *et al.* (1988) stated for the first time, that at present, Peloponnesus and Crete are dominated by approximately E–W extension and dip-slip movements along approximately N–S orientated faults. Our field data are in agreement with this. However, the last two groups could be equivalent to the episode ‘E’ shown in figure 6.

5. Discussion

The Cretan syn-orogenic detachment (Jolivet *et al.* 1996, 2003, 2013), running from the northern Peloponnese to the east of Crete is indicated between the Phyllite–Quartzite nappe and the overlying Gavrovo–Tripolitza nappe. This shallow-dipping extensional detachment was formed subparallel to a subjacent subduction thrust, in the early Miocene (Kiliass *et al.* 1994; Ring and Reischmann 2002). Moreover, it is associated with the formation of a supra-detachment basin of middle Miocene age (van Hinsbergen and Meulen Kamp 2006; Zachariasse *et al.* 2011). Reactivation as a post-orogenic detachment has been reported in the Peloponnese on the eastern margin of the Parnon Range (Jolivet *et al.* 2013). From the Pliocene

onwards, steep normal faults, trending N–S or NE–SW are in abundance in Crete.

Giouchtas Mt. is possibly a contractional feature (asymmetric anticline) in this supra-detachment basin of middle Miocene age, related to the above-mentioned stress fields (figure 6). The compressional stress fields, inferred by the present study, are also supported by other authors and might be associated to the crustal thickening that continued on Crete probably until some weakly-defined time in the late-middle Miocene (e.g., Mercier *et al.* 1989; Jolivet *et al.* 1994, 1996; ten Veen and Postma 1999; Jolivet and Brun 2010). Additionally, it is noted that our data are also in agreement with kinematics and structural data from the tectonic windows of eastern Crete and Dodecanese islands (Kokkalas and Doutsos 2004). Following the contraction tectonics, successive, distinct, extensional episodes took place creating six fault generations considered herein. Based on S_{mf} and V_f values, the study area is assigned to a tectonic class I, corresponding to the higher tectonic activity. This is also supported by previous studies (Delibasis *et al.* 1999; Kokinou *et al.* 2008) concerning the distribution of the microseismicity and seismotectonic structure for the broader area of Heraklion basin. The activity of the fronts (1) and (2) seem to be in agreement with the recent structural pattern corresponding to two generations of faults striking NE–SW and almost N–S, associated with the Pleistocene to recent times tectonic activity. Furthermore, the activity corresponding to fronts (3) and (4) is also high, suggesting that the northern part of Giouchtas Mt. is sinking to the north. This activity is related to the deposition of Quaternary to recent clastic sequences.

Figure 7. The most likely development stages of the Giouchtas Mt. (Mitra 2002): (a) growth of fold by rotation of limb segments possibly initiated in Eocene–early Oligocene and (b) propagation of the fault through competent units a, b, c, d (explanation in the text).

Taking into account the morphotectonic and structural analysis, the model of figure 7 (Mitra 2002) is proposed to explain the structural development of the present asymmetric anticline. An asymmetric detachment fold should be developed in a following rock package, characterized by high competency contrast between detachment and cover units. It consists of a thin incompetent detachment unit (a), possibly the basement of the study area, and thick competent units (b) and (c), prone to flexural, possibly differential slips. Finally, an uppermost thin moderately competent unit (d) seems to be prone to some internal strain. Fold growth involves limb rotations and hinge migrations in an early stage, possibly initiated in Eocene–early Oligocene, followed by fault propagation through the competent folded unit. This fault (figure 5b) temporarily ends within the deformation zone in the upper competent units of the forelimb and within the upper levels of the detachment unit. It eventually breaks through the whole forelimb and connects with basal detachment. Backlimb is also deformed by a back-thrust fault (figure 5a). Later extensional tectonics (figure 5c, d, e) further deformed the present, possibly active tectonic feature resembling the late Neogene contractional structures and related tectonic models presented by Chatzaras *et al.* (2006, 2013) and Tortorici *et al.* (2010).

6. Conclusions

In this work, a model is proposed concerning the structural development of a contractional structure (i.e., Giouchtas Mt.) in a supra-detachment basin. This model is derived by morphotectonic, stratigraphic, and structural analysis.

More specifically, the mountain fronts of the eastern and western flanks of Giouchtas Mt. generally correspond to low S_{mf} and V_f values, indicating active uplift of the study area, also supported by the structural results.

Giouchtas Mt. is an example of a pre-existing contraction-related structure that was strongly deformed in later stages by normal faulting, generated during extensional episodes from latest Serravallian–earliest Tortonian to subrecent times. These episodes indicate stress fields that influenced the area, with N–S trending direction since the latest Serravallian times at least, via NE–SW in early Tortonian, to WNW–ESE during early to middle Tortonian. The stress field changed to NW–SE in late Tortonian to early Pleistocene times and finally to ENE–WSW in middle Pleistocene to subrecent time-period. Moreover, the reactivation of normal faulting along the older, roughly E–W trending, extensional structures, during early

Messinian, is characterized by a dip slip component of movement. Finally, strain direction changes to ENE–WSW during middle Pleistocene to Holocene times, resulting in the deposition of the recent Quaternary to Holocene sequences.
