Abstract. Microsatellite loci were used for parentage identification of *Odontobutis potamophila* in five full-sib families. The combined exclusion probability of the first (E-1P) and the second parent (E-2P) revealed an obvious increase with the increase of number of microsatellite loci. The combined exclusion probability based on allele frequency suggested that at least eight microsatellite loci were needed for the identification of the 150 individuals from five families supported by the genetic distance analysis of individuals of these families. The double-blind test results indicated that the candidate individuals could find their correct parents through these loci thus eight microsatellite markers can be used for pedigree analysis of *O. potamophila* in breeding industry as well as for future selection studies.

Keywords. microsatellite DNA; parentage identification; Odontobutis potamophila.

Introduction

Odontobutis potamophila belongs to the family Odontobutidae, an important commercial fish species widely distributed in southeast China deeply favoured by people for its delicious taste, rich nutrition and therefore, has high economic value (Li and Liu 2014). However, because of environmental pollution, overfishing, and growing market demand, O. potamophila has undergone a severe reduction in population size and distribution (Zhu et al. 2014). Therefore, it is urgent to conduct geneticbased selective breeding of O. potamophila. The selective breeding is an effective strategy to improve variety selection in aquaculture. In breeding practices, to save space and capital, different lineages have frequently been bred together. As a consequence, it may result in inbreeding, thus reducing genetic diversity of offspring, therefore, limiting the potential for genetic gain from artificial selection and ultimately reduce the production performance. For the sake of avoiding the phenomenon of inbreeding and improving variety selection, it is extremely important to establish reliable pedigree information and identify the genetic relationship of different lineages to design breeding programmes to enhance desirable traits.

In the field of ecology, microsatellite loci were commonly used for the measurement of genetic variability within and between populations (Hartl and Clark 1989; Slatkin 1995). The relative ease of development and high allelic diversity make it ideal for individual genotyping in assisting pedigree identification (Guichoux et al. 2011), identifying unique individuals (Lukacs and Burnham 2005), and inferring phylogenetic or genealogical relationships in different groups of species (Blouin 2003). Microsatellitebased parentage identification technology has been widely used in determining genetic relationships in aquaculture, such as yellow catfish (Pelteobagrus fulvidraco) (Zhang et al. 2015), large yellow croaker (Larimichthys crocea) (Liu et al. 2013) and coral reef fish (Lutjanus carponotatus) (Hugo et al. 2014). All the offspring from different groups and families can be stocked together and assigned to their

Peipei Wang and Cheng Zhao contributed equally to this work.

original families and their potential parental genotypes retrospectively by using DNA markers such as microsatellites. In this way, there is no need to mark the progeny before stocking into ponds, known and unknown parent progeny relationships can be used to evaluate the identification capability of microsatellite DNA markers.

Materials and methods

Sample collection and pedigree establishment

The broodstock (1 year old) collected randomly from Xinan river in Dangtu of Anhui province, Jiande of Zhejiang province and Taihu of Suzhou of Jiangsu province were well developed, healthy and free from injury. The mean length and body weight of each individual was 12.79 ± 0.33 cm, and 32.25 ± 2.48 g, respectively. Twentyseven full-sib families (three replicates of each combination) were established and offspring from each family was recorded. Five full-sib families were selected randomly and denoted as the undetermined family. Progenies from each of these families were grown separately until they reached 5 cm in length. From each family, 30 individuals were selected and the tail fin was collected and stored in ethanol for subsequent experiments. Forty individuals from the rest of the offspring of five selected families (eight samples of each family) were selected, and their tail fin tissues were collected and stored in ethanol. All experiments were performed according to the guidelines for the Care and Use of Laboratory Animals in China. This study was also approved by the Ethics Committee of Experimental Animals at Nanjing Normal University.

DNA extraction and genotyping of microsatellite DNA markers

Genomic DNA was extracted from tail fin tissue using cell/tissue genomic DNA extraction kit (centrifugal column type, Generay Biotech, Shanghai). Fifty-six markers of O. potamophila have been developed in our laboratory (Wang et al. 2017). We selected eight SSRs among these 56 developed microsatellite loci, which show relatively higher polymorphism (OPRM 87, OPRM 114, OPRM 115, OPRM 117, OPRM 123, OPRM 125, OPRM 197 and OPRM 200) to genotype the offspring from five families and their original parents (table 1). A total of $10 \,\mu$ L of PCR mixture was prepared by 50 ng template DNA, 0.2 mM dNTPs, 1.5 mM MgCl₂, $10 \times$ PCR buffer, 1 U Taq DNA polymerase, $0.04 \,\mu\text{M}$ M13-tailed forward primer, $0.16 \,\mu\text{M}$ reverse primer and $0.16 \,\mu\text{M}$ fluorescence-labelled M13 primer. PCR was conducted under following conditions: initial denaturation at 95°C for 5 min, 30 cycles with the denaturation at 94°C for 30 s, annealing at various temperatures (table 1) for 30 s and extension at 72°C for 45 s, followed by eight cycles with the denaturation at 94°C for 30 s, annealing at 53°C for 45 s and extension at

72°C for 45 s, and a final extension at 72°C for 10 min. Subsequently, ABI 3500xl sequencer was used to analyse the PCR products and sizes were determined with GeneMapper ver. 4.1.

Statistical analysis

The genetic diversity parameters of eight SSR loci including the number of alleles (N_a) , observed heterozygosity $(H_{\rm o})$, expected heterozygosity $(H_{\rm e})$, polymorphism information content (PIC), frequency of null alleles (Null freq) and the exclusion probability without known parents (E-1P), and the exclusion probability with genotype of one parent known (E-2P) were estimated by Cervus 3.0 (Kalinowski et al. 2007). According to the genetic distance between each individual in the family, the NTSYS software was used for clustering analysis, which was used for analysing the relationship of different pedigrees. The selected five families were denoted as A, B, C, D and E, respectively. Transforming genotype data of each family into PopGene format through PopGene1.32 software is required, and the genetic distance analysis with PopGene1.32 software for the selected individuals was conducted for the evaluation of genetic consistency. The Excel software (2013) was used to transpose the genetic consistency tables into the TXT format through NTSYS software, and then used for clustering analysis for individuals by using NTSYS software according to the degree of genetic consistency.

Results

Genetic diversity of microsatellite DNA markers

Hundred and ninety individuals in total from five fullsib families of *O. potamophlia* were genotyped by eight SSR markers for genetic diversity parameters. The genotype of individuals, allele range, and null allele frequency (Null freq) are provided in table 2. The number of alleles (N_a) , observed heterozygosity (H_o) , expected heterozygosity (H_e) and the polymorphism information content (PIC) ranged from 4 to 9, 1.000 to 1.000, 0.602 to 0.833 and 0.521 to 0.824, respectively (table 3). All eight loci were highly polymorphic, with the PIC larger than 0.50 (Botstein *et al.* 1980).

Computed simulation

The E-1P and E-2P of each locus ranged from 0.187 to 0.554 and from 0.320 to 0.716, respectively (table 4). The locus OPRM 87 exhibited the highest value of PIC, E-1P and E-2P (0.824, 0.554 and 0.716, respectively), and revealed the lowest value of PIC, E-1P and E-2P (0.85, 0.575 and 0.732, respectively). As shown in figure 1, the

combined exclusion probability values, the E-1P was 97% and the E-2P was higher than 99%, when eight SSRs were selected and used. All results suggested that the eight SSRs we selected were sufficient for parentage analysis. What is more, if we use more microsatellite loci to perform parentage analysis, the higher accuracy of the analysis can be acquired.

Pedigree identification and double blind test

All experimental samples were clustered into the same branch, when parents and offspring belonged to the same family. Our study indicated that all parents and offspring from five families could distribute into the same branch appropriately (figure 2). As a result, the selected microsatellite DNA markers can distinguish the different families. For the double-blind test, a total of 40 offspring from five families (eight individuals of each family) were randomly selected. All progenies were allocated to five branches separately which is indicated by UPAGE dendrogram (figure 3). The accuracy of clustering reached up

to 100% and all individuals from the same family were clustered together.

Discussion

In aquaculture, selective breeding programme is important and it is necessary to select suitable markers for maintaining correct pedigree relationships. Many conventional methods, such as, physical tags and electronic tags have several shortcomings in breeding programme (Jerry et al. 2004). Biological tags have a potential power to resolve the limitations of conventional methods. In present study, we demonstrated that both parents and offspring could be determined in the absence of physical tags and pedigree information in a mixed population. The application of microsatellite DNA markers to identify and determine the genetic relationship has gained recognition and attention in aquaculture because microsatellite DNA marker with rich polymorphism is a simple way to determine the heredity. For example, four microsatellite DNA markers were used for parentage analysis in the 100 breeding individuals of rainbow trout, and 91% of the offspring were assigned to their true parents (Herbinger et al. 1995). In mandarin fish, 10 microsatellite DNA markers have been used for parentage determination (Yang et al. 2014), and a total of 180 individuals of yellow catfish in eight full-sib families have also been successfully identified with nine microsatellite DNA markers (Zhang et al. 2015). The study of parentage identification in O. potamophlia has not been reported yet. Therefore, we identified and analysed the genetic relationship of five O. potamophlia families through eight microsatellite DNA markers. The development of parentage identification through microsatellite loci depends on

Figure 2. The clustering analysis of the parents and offspring from five families.

Figure 3. The clustering analysis of five polyculture offspring and parents.

the microsatellite polymorphism information, the ability of exclusion and the size of the candidate parents and offspring (Norris et al. 2000). A large number of candidate parents and offspring need more microsatellite loci to evaluate the parentage relationship between them (Vandeputte et al. 2011). As the result, before the markers were employed, it is essential to conduct simulation evaluation. which will benefit for estimating the actual number of loci and the potential performance of these markers. In the present study, all results showed that the increasing number of the selected microsatellite DNA markers and the polymorphism could result in the higher cumulative exclusion rate. When the selected markers reached up to eight, each of progeny was assigned to their correct parents (figures 2 and 3), and the exclusion probability was also increased to 99.8%. In this study, the observed heterozygosity was higher than expected heterozygosity in five families. This might be caused by the following reasons: (i) the population of O. potamophila has a number of homozygous individuals; (ii) the families were not mating randomly, which result in excess of heterozygotes and deviate from the Hardy–Weinberg equilibrium; (iii) the loci in this study have a high mutation rate, which produced many different alleles; and (iv) errors might cause due to inadequate sampling individuals (Dakin and Avise 2004; Ellegren 2004; Jerry et al. 2004). The null alleles had slight impact on the accuracy of assignment owing to the fact that the frequency of null alleles was relatively low. If enough markers were selected, all offspring can be explicitly allocated to their own parents in practical study. What is more, the assignment success rate was high in our study, which also indicates the validation of our selected microsatellite loci. These eight microsatellite markers in this study will facilitate maintaining pedigree information and family-selected breeding of *O. potamophlia* in the future.
