Abstract. Estimation of the turbulent dissipation rate in a boundary layer is a very involved process. Experimental determination of either the dissipation rate or the Taylor microscale, even in isotropic turbulence, which may occur in a portion of the turbulent boundary layer, is known to be a difficult task. For constant pressure boundary layers, a model for the turbulent dissipation rate is proposed here in terms of the local mean flow quantities. Comparable agreement between the estimated Taylor microscale and Kolmogorov length scale with other data in the logarithmic region suggests usefulness of this model in obtaining these quantities experimentally.

Keywords. Boundary layers; dissipation rate; Kolmogorov length scale; Taylor microscale.

1. Introduction

Estimation of the turbulent dissipation rate, \( \varepsilon \), of the kinetic energy requires the gradients of velocity fluctuations in a boundary layer. While direct numerical simulation (DNS) (although computationally intensive) provides the turbulent dissipation rate accurately, it is not so easily realizable in experiments [1, 2]. Stanislas et al [1] have very briefly mentioned difficulties in measuring the turbulent dissipation rate. These authors and Herpin et al [3], for example, find the isotropic condition to be a good approximation in the logarithmic region. However, measurement of the Taylor microscale remains a difficult task, as it involves correlation function [1]. Consequently, an appreciation of the Taylor microscale, dissipation rate, etc., is lacking in practice due to complexity involved in estimating these quantities. Segalini et al [2] have proposed a novel means for measuring the Taylor microscale from two hot-wire measurements. Once the Taylor microscale is available, the turbulent dissipation rate can be estimated, at least for isotropic turbulence. Alternatively, if a model for the turbulent dissipation rate is available, then the Taylor microscale can easily be estimated, as proposed in this paper. This model is in terms of easily measurable mean flow quantities and the estimated Taylor microscale and the Kolmogorov length scale are found to be comparable with other data in the logarithmic region of a constant pressure boundary layer.

2. Analysis

A zero-pressure gradient boundary layer over a plate that is placed in a free-stream velocity of \( U_\infty \) is considered here. The streamwise and the wall-normal distances are denoted by \( x \) and \( y \), respectively. The mean velocity components in these directions are \( u \) and \( v \), respectively; \( u' \) and \( v' \) are the corresponding fluctuating velocity components; the root-mean-square of \( u' \) is \( u'_{rms} = \sqrt{\frac{u'^2}{2}} \).

From a balance between the production and the turbulent dissipation rates in the logarithmic region, the turbulent dissipation rate is [4]

\[
\varepsilon = \frac{u'^3}{ky}, \quad (1)
\]

where \( u_c \) is the friction velocity, and \( \kappa \) is the Karman constant. In arriving at this turbulent dissipation rate, the two conditions used are: (i) \( \overline{u'v'} = u'^2 \), and (ii) \( du/dy = u_c/k_y \) from the log profile,

\[
\frac{u}{u_c} = \frac{1}{\kappa} \ln \left( \frac{y u_c}{v} \right) + B, \quad (2)
\]

where \( B \) is constant, and \( v \) is the kinematic viscosity; \( \overline{u'v'} \) is the Reynolds shear stress. This classical dissipation rate can also be interpreted, as follows.

From the inner law, \( u^+ = y^+ \), the wall vorticity is \( \Omega_w = u_c^2/v \); where \( u^+ = u/u_c \) and \( y^+ = y u_c/v \). Under the boundary layer approximation, the spanwise vorticity is \( \Omega_z \sim \partial u/\partial y \). For the log-profile in Eq. (2), \( \Omega_z \sim u_c/k_y \).
Expressing the dissipation rate in Eq. (1) in terms of these quantities, we have

$$\epsilon = \nu \left( \frac{u_\tau^2}{v} \right) \frac{u_\tau}{K} \sim \nu \Omega_\epsilon \Omega_\epsilon.$$  

(3)

One can thus interpret that du/dy is weighted by the wall vorticity.

Blair and Bennet [5] consider $u_\tau$ and y as ‘energy containing’ scales near the wall. Assuming a balance between the dissipation and production rates of the turbulent kinetic energy, they take the dissipation rate as

$$\epsilon \approx \frac{\tau}{\rho} \frac{\partial u}{\partial y} = \frac{\nu}{\gamma} \frac{\partial^2 u \Sigma}{\partial y^2},$$

(4)

where \( \tau \) is the shear stress, \( \rho \) is the density, and \( c \) is a constant. Since the turbulent dissipation rate mostly depends on \( u_\tau \) and y scales, a quantity that is \( O(u_\tau) \) may also be considered in defining the dissipation rate. Interestingly, we find that the quantity \( (u^+u_{rms}^+) \) is of-the-order of \( u_\tau^2 \) in the logarithmic region as shown in figure 1, where the variation of \( (u^+u_{rms}^+) \) in the boundary layer is shown for the DNS data of Schlatter and Örlü [6] and experimental data of DeGraff and Eaton [7]. \( Re \) denotes Reynolds number based on the momentum thickness; \( u_{rms} = u_{rms}/u_\tau \).

It can be seen that the quantity \( (u^+u_{rms}^+) \sim \text{constant} \) in the log-layer; the deviation seen at higher Reynolds number is due to the fact that the outer peak in the distribution of \( u_{rms} \) becomes noticeable at higher Reynolds numbers. That is, \( (u^+u_{rms}^+) \) in the log-layer is an approximate measure of the skin-friction; this result is new, to the best of our knowledge. In the near wall region the variation is linear in this log–log plot.

Based on the above-mentioned points, we consider the dissipation rate as

$$\epsilon \sim \nu \left( \frac{u_\tau^2}{v} \right) \left( \frac{uu_{rms}}{y} \right)^{1/2}.$$  

(5)

That is, \( (uu_{rms})^{1/2}/y \), which is \( O(u\tau/y) \), has been weighted by the wall vorticity, as in Eq. (3). For isotropic condition, which is a good approximation in the log-layer [1, 3], \( u_{rms} \) is the characteristic velocity scale [4]. The inclusion of \( u_{rms} \) in this model is for this reason. Since \( (uu_{rms})^{1/2} \sim O(u_\tau) \) in the log-layer, the proposed model for the dissipation rate in Eq. (5) preserves the essence of Eqs. (1) or (4). At the boundary layer edge, \( y \rightarrow \delta \) and \( u \rightarrow U_\infty \). So \( \Omega_\epsilon \sim u_\tau/y \) is non-zero. However, \( u_{rms} \) being very small at the boundary layer edge, the quantity \( (uu_{rms}/y^2)^{1/2} \) also tends to be small and is caused by the vorticity scale \( u_{rms}/y \) (in terms of the characteristic velocity). In terms of the boundary layer thickness, \( \delta \), and \( u_\tau \), the non-dimensional turbulent dissipation rate is

$$\frac{\epsilon \delta}{u_\tau^2} = A \delta^+ \left( \frac{uu_{rms}}{y^2} \right)^{1/2}.$$  

(6)

Here \( \delta^+ = u_\tau \delta/v \). With the constant \( A = 0.41 \), which seems to be equal to the Karman constant, the model turbulent dissipation rate is found to cover a large portion of the boundary layer, including the \( \epsilon \sim \text{constant} \) region, as shown in figure 2. While this turbulent dissipation model is expected to work well in the logarithmic region, it is a good model for the near wall region, as well. This interesting aspect is attributed to the following. Since \( u \sim y \) and \( u_{rms} \sim y \), as \( u \sim y \), near the wall, one expects \( (uu_{rms})^{1/2} \sim y^+ \) there, as shown in figure 1. The model equation (6) thus yields a constant dissipation rate near the wall. Figure 2 shows that the proposed model for the turbulent dissipation rate, though based on a different consideration, can represent the dissipation rate quite accurately over a large portion of the boundary layer; it is noteworthy that \( A = 0.41 \) holds good over this region. The foregoing discussion suggests that \( uu\delta^+ \) and \( uu_{rms} \) may not be totally unrelated.

For constant pressure turbulent boundary layers, the decomposition of the skin-friction coefficient, \( C_f \), proposed by Fukagata et al [8] is

$$C_f = \frac{4(1 - \delta^+)}{Re_\delta} + 4 \int_0^1 (1 - Y)(-u\bar{v})_1 dY$$

$$- 2 \int_0^1 (1 - Y)^2 I_x + \frac{\partial U}{\partial t} dY.$$  

(7)

Here \( Y = y/\delta, U = u/U_\infty, (u\bar{v})_1 = u\bar{v}/U_\infty \), and \( \delta^+_i (= \delta'/\delta) \) is the non-dimensional displacement thickness. \( I_x \) is the inhomogeneous term that contains the inertial part and the streamwise diffusion term, and \( Re_\delta (= U_\infty \delta/v) \) is the Reynolds number based on the boundary layer thickness. While the meaning of the first term in the right-hand-side of Eq. (7) is not clear in the case of plane boundary layers, it is

---

**Figure 1.** Variation of \( (u^+u_{rms}^+) \) in the boundary layer. Schlatter and Örlü [6]: ---, \( Re = 2540 \); ---, \( Re = 4060 \). DeGraff and Eaton [7]: \( \triangle, Re = 2900 \); \( \square, Re = 5160 \); \( \circ, Re = 13310 \); \( \bullet, Re = 30850 \).
This decomposition of the skin-friction suggests that the laminar skin-friction term in pipe and channel flows. Figure 2. Comparison of the estimated dissipation (symbols) with DNS (lines) and experiments [1] using Eq. (6). Schlatter and Orlt [6]: +, Re = 2540; ×, Re = 4060. Stanislas et al [1]: ○, Re = 8200; ●, Re = 20800. Lines and other symbols as in figure 1.

the laminar skin-friction term in pipe and channel flows. This decomposition of the skin-friction suggests that the Reynolds shear stress, \(-\rho(u'v')\), is weighted by the term \((1 - Y)\). Now, by definition, the momentum thickness, \(\theta\), is

\[
U_\infty \theta = \int_0^\infty u(U_\infty - u)dy.
\]

Also, the momentum integral equation for a constant pressure boundary layer is

\[
\frac{d\theta}{dx} = \frac{d\delta}{dx} \int_0^1 U(1 - U)dy = \frac{C_f}{2}.
\]

Comparing this with Eq. (7), one can infer that \((u'v')\) may have some contribution to the local momentum deficit, \(U(1 - U)\). Since, for a given Reynolds number, the quantity \((1 - Y)/u'\) \((U_\infty - u^+)\) is nearly constant in the log-layer, as shown in figure 3, and \(u'v' \sim u^2\) there, \(U(1 - U)\) may be related to \((1 - Y)u'v'\) almost directly. As both \((u'v')\) and \((u_{rms})\) being of \(O(u^2)\), we find the correlation,

\[
\frac{-u'v'}{[u^+(U_\infty - u^+)]^{1.25}} \approx 4.25 \times 10^{-5} \frac{(u^+u_{rms})}{(1 - Y)^{1.038}}
\]

provides a good correspondence between these two terms, as shown in figure 4. Here again \((1 - Y)^{1.038}/[u^+(U_\infty - u^+)]^{1.25}\) is nearly constant in the logarithmic region, as shown in figure 5.

We now consider the dissipation rate for the isotropic case,

\[
\epsilon = 30\frac{u_{rms}^2}{\ell^2},
\]

used by Stanislas et al [1]. Using the present dissipation model in Eq. (6), the Taylor microscale that follows for the isotropic case is

\[
\lambda = \left(\frac{30}{4}\right)^{1/2} \left(\frac{\nu}{u^+}\right)^{1/2} \left(\frac{u_{rms}}{u^2\Lambda u_{rms}}\right)^{1/4}.
\]

Noting that \(y/u^+\) is a time scale, one can identify \((\nu y/u^+)\) \((1/2)\) \((\nu y)\) \((1/2)\) \((u_{rms})\) \((3/4)\) \((u^+)\) \((1/4)\). That is, this differs from Alfredsson et al [9] by the factor \((u_{rms})^{3/4}/(u^+)\). However, the variation of \((u_{rms})\) \((3/4)\) \((u^+)\) \((1/4)\) being slow in the logarithmic region, compared to \((y)\) \((1/2)\), its contribution seems to be small. The data of Segalini et al [2] (taken from their figure 8) shown in figure 6 is multiplied by a factor of 1.6 for it to be closer to other data in this figure. The estimated variation of the Kolmogorov length scale, \(\eta = (\nu y)^{1/4}\), shown in figure 7 is similar to the measured values of Stanislas et al [1] and Herpin et al [3], and is close to \(\eta^+ = (\nu y)^{1/4}\) in the log-layer.

A very interesting finding of Herpin et al [3] is that \(\Omega_\varepsilon\) scales with the Kolmogorov time scale, \((\nu y)^{1/2}\), in the log-layer; specifically, they suggest \(\nu\Omega_\varepsilon^2 \approx \epsilon\). With \(u^+\) and \((\nu y/u^+)\) \((1/2)\) as the characteristic velocity and length scales, we can see in figure 8 that

\[
\left(\frac{\nu}{u^+}\right)^{1/2} \left(\frac{\nu}{\epsilon}\right)^{1/2} = \left(\frac{1}{(\nu y)^{1/2}}\right) \approx \text{constant},
\]

in the logarithmic region; here DNS [6] and measured [1, 3] data are used for \(\epsilon\). The values estimated using Eq. (6) are also shown for \(Re = 2540\) [6]. Thus, in terms of \(\Omega_\varepsilon\) and \(\Omega\), we have

\[
\nu\Omega_\varepsilon\Omega^2 \approx \epsilon,
\]

as in Eq. (3). This is similar to that of Herpin et al [3], except that they consider \(\Omega^2\). Now, considering the length
We have the velocity scale \(v_y = u_s\) and the time scale \(y = u_s\). Thus, the scaling of \(\epsilon = u_s v_y / y\) is
\[
\left(\frac{v_y}{y}\right)^{1/2} \left(\frac{y_v}{v_y}\right)^{1/2} \left(\frac{v}{\epsilon}\right)^{1/2} = \left(\frac{v \Omega^2}{\epsilon}\right)^{1/2}.
\] (15)

That is, \(\epsilon \approx v \Omega^2\) of Herpin et al. \([3]\) is arrived at by scaling \((v/\epsilon)^{1/2}\) with the time scale \(\Omega_t \sim (u_s/y)\). Thus, \(\epsilon \sim v \Omega_t \Omega_w\) or \(\epsilon \sim v \Omega^2\) may depend on the choice of the velocity and length scales; as \(\epsilon \sim y^{-1}\) in the logarithmic layer, \(c_y = \text{constant}\) is expected. Thus the proposed model seems equally good in the scaling of \((v/\epsilon)^{1/2}\) with \(\Omega_t\). It may be noted that, with \(\Omega_t \sim \partial u / \partial y\), and \(\epsilon \sim y^{-1}\) in Eq. (14) leads to \(u \sim \ln(y)\).
3. Conclusion

In summary, a model for the turbulent dissipation rate is proposed from a finding that \((u'u_{\text{rms}}) \sim u^2\) in the logarithmic region of a constant pressure boundary layer. This model is in terms of easily realizable mean flow quantities and can predict the turbulent dissipation rate over a large portion of the boundary layer, including the region of \(\epsilon \approx \text{constant}\). An alternative and easy means of experimentally measuring the Kolmogorov length scale and the Taylor microscale in the logarithmic region follows from this model for the turbulent dissipation rate.
