Abstract. This paper presents the small-signal stability analysis of an 11-kW open-loop inverter-fed induction motor drive, including the effect of inverter dead-time. The analysis is carried out using an improved small-signal model of the drive that has been reported in literature recently, and is used to demonstrate small-signal instability in a higher-power-level motor. Through small-signal stability analysis, the region of oscillatory behaviour is identified on the voltage versus frequency plane (V - f plane), considering no-load. These predictions using the improved model are also compared against predictions of a standard model of an inverter-fed induction motor including dead-time effect. The oscillatory behaviour of the 11-kW motor drive is also studied through extensive time-domain numerical simulations and actual measurements over wide ranges of operating conditions. Both the simulation and experimental results confirm the validity of the predictions by the improved analytical model. Further, these results establish that the analysis is valid for both sine-triangle pulse-width modulation (PWM) and conventional space vector PWM.

Keywords. Dead-time; induction motor; voltage source inverter; small-signal model; stability.

1. Introduction

Induction machines are widely used in the industry for various applications such as fans and pumps. Energy efficiency considerations have led to variable-speed operation of fans and pumps rather than fixed-speed operation. Open-loop volt-per-hertz (V/f) control is a simple control scheme for such applications. V/f control of induction motors is also widely employed in the industry during the testing stage of inverters and induction motors. A schematic of an open-loop inverter-fed induction motor with a simple V/f control is shown in figure 1.

A number of open-loop V/f induction motor drives have been reported to exhibit oscillatory behaviour at low and medium speeds, and particularly under light-load conditions [1–10]. This light-load instability phenomenon is impacted by motor parameters such as stator and rotor resistances, leakage and magnetising reactances and inertia [1, 3, 10]. Increased stator resistance of the motor is an important factor, which results in this light-load instability [2–5]. Further, the inverter dead-time, which is introduced for safe commutation of switches in an inverter, is reported to result in or accentuate these sub-harmonic oscillations in

the induction motor [4–9]. Recently, inverter dead-time was shown to result in significant sustained sub-harmonic oscillations in a 100-kW induction motor [7–9].

Considering the importance of V/f drives in the industry, this paper attempts to study the prevalence of such oscillations in commercial motor drives. Specifically, a case study on an 11-kW industrial motor drive is reported in this paper. The study presented here is a collaborative effort between an industry and an academic institution. This study comprises small-signal stability analysis, time-domain numerical simulations and actual measurements on an 11-kW motor drive. The main objective here is to predict the region of oscillatory behaviour, if any, of the 11-kW induction motor.

The small-signal stability analysis of induction motor is carried out by linearising its dynamic model about an equilibrium point. The standard or classical approach to stability analysis is to linearise the standard dynamic model of the induction motor available in textbooks and in literature [1, 11]. However, the stator resistance is taken as the sum of actual resistance (r_s) and an additional resistance R_{eq0} , considered to include the dead-time effect [5–7]. This dead-time equivalent resistance depends on the dead-time error voltage [5, 7, 12, 13] and stator current. An accurate

Figure 1. Schematic representation of an open-loop induction motor drive.

method to evaluate this equivalent resistance is presented in [14].

Recently, a more rigorous analysis of the dead-time effect on the inverter output has led to an improved small-signal model for the inverter-fed induction motor [9]. The dead-time effect on the inverter output has been studied in the synchronous dq reference frame [15, 16]. This has led to a modified dynamic model of the inverter-fed induction motor [14]. Linearisation of this modified dynamic model has resulted in an improved small-signal model for stability analysis. The improved and standard small-signal models are reviewed in section 2 of this paper.

Both the improved and standard small-signal models are used to perform the stability studies on the 11-kW induction motor drive, in section 3. These models are used to predict the regions of oscillatory behaviour of the 11-kW drive. Evaluation of the validity of the two models is another objective here. Extensive simulation results presented in section 4 validate the small-signal analysis and the region of oscillatory behaviour as predicted by the improved small-signal model. An extensive experimental study on the 11-kW induction motor, presented in section 5, confirms the oscillatory behaviour in the drive as predicted by the improved model. A preliminary version of this paper was presented in [17]. This full paper presents additional analytical, simulation and experimental results for different ratios of dead-time to switching cycle time so that more general conclusions could be drawn.

2. Review of small-signal model of an open-loop induction motor drive

The dynamic model of the induction motor drive [14] and the linearised small-signal models of the drive [5, 8, 9] are reviewed in the following subsections.

2.1 Modified induction motor dynamic equations

Inverter dead-time is known to cause an error voltage pulse in each switching cycle, the polarity of which depends on the load current polarity [12, 13]. The switching-cycle average of this error voltage is seen to be

a square wave over a fundamental cycle; the polarity of this square wave depends on the sign or polarity of the load current [12, 13]. The dead-time error voltages are analysed in the synchronous dq reference frame in [15, 16]. In [15], the fundamental components of the dead-time error voltages in the RYB reference frame are considered, and are transformed to the dq reference frame, resulting in error voltage drops that depend on the q -axis and d -axis inverter output currents. These error voltage drops are incorporated into the stator dynamic equations, which can be rewritten as follows [14]:

$$v_{qs,id} = \left(r_s + \frac{|\vec{V}_{s,err,f}|}{\sqrt{i_{qs}^2 + i_{ds}^2}} + L_s \frac{d}{dt} \right) i_{qs} + \omega_s L_s i_{ds} + L_m \frac{di'_{qr}}{dt} + \omega_s L_m i'_{dr} \quad (1)$$

$$v_{ds,id} = -\omega_s L_s i_{qs} + \left(r_s + \frac{|\vec{V}_{s,err,f}|}{\sqrt{i_{qs}^2 + i_{ds}^2}} + L_s \frac{d}{dt} \right) i_{ds} - \omega_s L_m i'_{qr} + L_m \frac{di'_{dr}}{dt} \quad (2)$$

Here, i_{qs} and i_{ds} are the q -axis and d -axis stator, respectively. For any continuous pulse-width modulation (PWM) scheme such as sine-triangle PWM (SVPM) or conventional space vector PWM (CSVPM), the magnitude of the dead-time error voltage vector is given by (3)

$$|\vec{V}_{s,err,f}| = \frac{4}{\pi} V_{dc} t_d f_{sw} \quad (3)$$

where V_{dc} is the dc bus voltage, t_d is the inverter dead-time and f_{sw} is the switching frequency [14, 16]. Further, $v_{qs,id}$ is the ideal q -axis stator voltage applied by an ideal inverter without dead-time. Since the ideal voltage vector is aligned along the q -axis, its component $v_{ds,id}$ along the d -axis is zero. The rotor voltage equations and the mechanical dynamic equations are the standard equations as given in [8, 9, 11]. These equations together constitute the modified dynamic model of an induction motor, including the dead-time effect [14].

2.2 Small-signal model

The improved small-signal model is derived by linearising the modified dynamic equations of the induction motor [14] about a steady operating point. The determination of the steady-state solution/operating point including the effect of dead-time is presented in [14].

The linearised small-signal model of an inverter-fed induction motor with significant dead-time can be expressed in the standard form [9] as follows:

$$\Delta \dot{\mathbf{x}} = \mathbf{A} \Delta \mathbf{x} + \mathbf{B} \Delta \mathbf{u} \quad (4)$$

where

$$\mathbf{A} = \begin{bmatrix} -\mathbf{L}^{-1}\mathbf{R} & -\mathbf{L}^{-1}\lambda_{10} \\ \left(\frac{3}{2J}\right)\left(\frac{poles}{2}\right)^2 \lambda_{20}^T & -\frac{B}{J} \end{bmatrix} \quad (5)$$

The various constituent matrices are given in [9], and are reproduced in the appendix of this paper. The specific constituent matrix, whose elements are impacted by the inverter dead-time, is the matrix $\mathbf{R}$, which may be expressed as follows:

$$\mathbf{R} = \begin{bmatrix} \mathbf{R}_{ss} & \mathbf{R}_{sr} \\ \mathbf{R}_{rs} & \mathbf{R}_{rr} \end{bmatrix} \quad (6)$$

More specifically, it is the sub-matrix $\mathbf{R}_{ss}$ in (6) that is directly influenced by dead-time. This sub-matrix $\mathbf{R}_{ss}$ is

Table 1. Induction motor parameters (star equivalent).

r_s (stator resistance)	0.333 Ω
r'_r (rotor resistance referred to stator side)	0.359 Ω
L_s (stator inductance)	82.46 mH
L'_r (rotor inductance referred to stator side)	84.94 mH
L_m (mutual inductance)	79.82 mH
J (inertia)	0.0685 kgm ²

described differently in the standard [5, 6] and improved small-signal models [9].

2.2a Standard small-signal model: In steady state, the effect of dead-time is seen as an equivalent resistance (R_{eq0}) that adds to the stator resistance of the motor [5–7]. In the standard model [5], the dead-time equivalent resistance (R_{eq0}) is just added to the stator resistance r_s . The $\mathbf{R}_{ss}$ sub-matrix used in the standard model is given below as follows:

Figure 2. Loci of the eigenvalues of an 11-kW inverter-fed induction motor under no-load for a speed range of 5–50 Hz considering (a) no-dead-time effect, (b) the standard model with $t_d = 3 \mu\text{s}$ and $f_{sw} = 5 \text{ kHz}$ (i.e. $t_d f_{sw} = 0.015$) and (c) improved model with $t_d = 3 \mu\text{s}$ and $f_{sw} = 5 \text{ kHz}$ (i.e. $t_d f_{sw} = 0.015$). A dc bus voltage of $V_{dc} = 600 \text{ V}$ and a V/f ratio of 0.89 pu are considered in the analysis.

Figure 3. Stable and unstable equilibrium points in the V - f plane for an 11-kW induction motor drive under no load, as predicted by the standard small-signal model [5], considering $V_{dc} = 600$ V and $t_{dfsw} = 0.024$.

$$\mathbf{R}_{ss,std} = \begin{bmatrix} r_s + R_{eq0} & \omega_{s0}L_s \\ -\omega_{s0}L_s & r_s + R_{eq0} \end{bmatrix}. \quad (7)$$

2.2b Improved small-signal model: As mentioned earlier, the improved small-signal model [9] is obtained by linearising the modified dynamic equations of the induction motor, which includes Eqs. (1)–(3). The sub-matrix $\mathbf{R}_{ss}$ in the improved small-signal model, thus derived, turns out to be as follows:

$$\mathbf{R}_{ss,impr} = \begin{bmatrix} r_s + R_{q,eq0} & \omega_{s0}L_s - X_{qd,eq0} \\ -\omega_{s0}L_s - X_{qd,eq0} & r_s + R_{d,eq0} \end{bmatrix} \quad (8)$$

where

$$R_{q,eq0} = R_{eq0} \left(\frac{i_{ds0}^2}{i_{qs0}^2 + i_{ds0}^2} \right); R_{d,eq0} = R_{eq0} \left(\frac{i_{qs0}^2}{i_{qs0}^2 + i_{ds0}^2} \right)$$

$$X_{qd,eq0} = R_{eq0} \left(\frac{i_{qs0}i_{ds0}}{i_{qs0}^2 + i_{ds0}^2} \right); R_{eq0} = \frac{|\vec{V}_{s,err,f}|}{\sqrt{i_{qs0}^2 + i_{ds0}^2}}.$$

The improved small-signal model suggests that the dead-time effect is more than just an equivalent resistance in series with the stator resistance, unlike what is portrayed by the standard model. The improved model shows that dead-time effect contributes to different values of q -axis and d -axis resistances, and also cross-coupling reactance terms between the two axes. These equivalent resistances and reactances appear from the linearisation of the dead-time error voltage terms in the stator dynamic equations. An evaluation of the validity of the two models in predicting the oscillatory behaviour of the 11-kW drive is an objective of the paper.

3. Small-signal stability analysis of an 11-kW motor drive

Stability analysis of an 11-kW, 21-A, 415-V, 4-pole, 50 Hz, three-phase induction motor (parameters in table 1) is carried out over a wide operating range. An operating point of the motor drive is defined by the fundamental or modulating frequency, applied voltage and load torque. Since oscillatory behaviour of the motor drives is known to be largely under light loads [4, 5, 9], the analysis is limited to no-load conditions here. The range of fundamental frequency considered is from 5 Hz to 50 Hz. The corresponding range of fundamental voltage depends on the V/f ratio chosen. While rated V/f ratio (i.e. $V/f = 1$ pu) is usually employed, the motor drive is also operated in under-flux conditions at light loads. Hence V/f ratio as low as 0.5 pu is considered for the analysis. For a given applied frequency and voltage, the steady-state solution of the drive including the effect of dead-time is determined first [14]. The steady values of state variables, along with the motor parameters and dead-time equivalent resistance, yield the elements of the small-signal stability matrix $\mathbf{A}$. The eigenvalues of matrix $\mathbf{A}$ are then evaluated to determine the small-signal stability of the drive at the given operating point.

When the dead-time effect is ignored (i.e. ideal case), the eigenvalues of matrix $\mathbf{A}$ vary with fundamental frequency as shown in figure 2a for a V/f ratio of 0.89 pu. A dc bus voltage of 600 V, a typical switching frequency f_{sw} of 5 kHz and a dead-time of 3 μ s are then considered. When the dead-time effect is incorporated as suggested by the standard small-signal model [5], the eigenvalues of matrix $\mathbf{A}$ change with the fundamental frequency as shown in figure 2b, for the same V/f ratio of 0.89 pu. While the root loci obtained with standard model (figure 2b) are significantly different from those with the ideal case (figure 2a), all eigenvalues are to the left of the $j\omega$ -axis in both cases for all frequencies. However, when dead-time effect is incorporated as proposed by the improved small-signal model [9], a complex conjugate pair of root loci traverses to the right of the $j\omega$ -axis for fundamental frequencies between 10 and 30 Hz. Thus, the improved small-signal model suggests oscillatory behaviour of the motor drive in the speed range between 10 and 30 Hz, at a V/f ratio of 0.89 pu. This will be verified through simulations and experiments in the later sections of the paper.

This analysis is repeated for different values of V/f ratios between 0.5 and 1 pu. Also, different values of f_{sw} and/or t_d that are of interest need to be considered. As seen from Eq. (3), the magnitude of dead-time error voltage depends on the product t_{dfsw} , at any given V_{dc} . Hence, apart from the value $t_{dfsw} = 0.015$, one lower value of 0.006 and a higher value of 0.024 are considered.

The unstable operating points (corresponding to different V/f ratios and fundamental frequencies) may be identified

on the V - f plane through the stability analysis discussed earlier. Considering the ideal case without dead-time, no unstable operating points are seen in the V - f plane. Considering a standard model where dead-time is just an equivalent resistance, no unstable operating points are seen with $t_{df_{sw}} = 0.006$, and $t_{df_{sw}} = 0.015$. However, there is a small region of instability when $t_{df_{sw}} = 0.024$ as shown in figure 3.

On the other hand, when the stability analysis is performed using the improved small-signal model, significant regions of instability are identified on the V - f plane for $t_{df_{sw}} = 0.006$, $t_{df_{sw}} = 0.015$ and $t_{df_{sw}} = 0.024$ as shown in figure 4a, b, and c, respectively. The region of oscillatory

behaviour is found to expand as $t_{df_{sw}}$ product increases. The boundaries of the regions of instability are shown for different values of $t_{df_{sw}}$ in figure 4d.

The analytically predicted region of instability of the 11-kW motor drive is verified through time-domain simulations in the following section.

4. Simulation results

The simulation model essentially consists of the standard dynamic equations of the induction motor in the synchronous dq -reference frame [11], whose inputs are fed

Figure 4. Stable and unstable equilibrium points in the V - f plane for an 11-kW induction motor drive under no load, as predicted by the improved small-signal model [9], considering $V_{dc} = 600$ V and (a) $t_{df_{sw}} = 0.006$, (b) $t_{df_{sw}} = 0.015$ and (c) $t_{df_{sw}} = 0.024$. (d) Variation of the region of instability with $t_{df_{sw}}$ for the given dc bus voltage. The stability analysis is limited to frequencies between 0.1 and 1 pu, and for V/f ratios between 0.5 pu and 1 pu. The frequency base is 50 Hz, and the line to line voltage base is 415 V.

from an inverter model including the dead-time effect. The ideal sinusoidal inverter output voltages are modified by adding the square-wave error voltages on account of inverter dead-time [5, 7]. The resultant inverter output voltages are transformed to voltages in the synchronous dq reference frame [16] and fed to the standard induction motor dynamic model.

For the simulations, the 11-kW induction motor (parameters in table 1) and $t_{dfsw} = 0.015$ are considered initially. The simulated waveforms at the operating point A (in figure 4b), i.e. at fundamental frequency $f_1 = 20$ Hz, and $V/f = 0.89$ pu, are shown in figure 5. Low-frequency oscillations of about 10 Hz are observed in the q -axis and d -axis currents in the steady state, indicating the operating point A to be unstable. These q -axis and d -axis currents are expected to be constant in the steady state for a stable operating point. These oscillations in the q -axis and d -axis currents reflect in the amplitude of the R -phase current shown in the same figure. Low-frequency 10 Hz oscillations are also seen in the motor torque and speed. It is observed that the torque developed is both positive and negative, indicating motoring and generating operation, respectively. Correspondingly, the rotor speed also accelerates and decelerates about the synchronous speed.

Simulations are repeated at various operating points in the V - f plane (corresponding to different fundamental speeds and V/f ratios) to identify the set of unstable operating points. The oscillatory region on the V - f plane may be identified for different values of t_{dfsw} . The regions of oscillatory behaviour for $t_{dfsw} = 0.006$, $t_{dfsw} = 0.015$ and $t_{dfsw} = 0.024$ obtained through simulations are shown in figure 6a, b and c, respectively. An unstable operating point is indicated by a shaded circle in the V - f plane. These regions of oscillatory behaviour, determined using the simulation model, are in very good agreement with the corresponding regions predicted by the improved small-signal model in figure 4a, b and c.

5. Experimental results

The experimental set-up consists of a three-phase, 415-V, 21-A, 11-kW, squirrel cage induction motor, fed from a two-level IGBT-based voltage source inverter, as mentioned before. The voltage source inverter is initially switched at a frequency of 5 kHz, and the inverter dead-time is 3 μ s. The dc bus voltage is set to 600 V using a controlled voltage source. The V/f control is implemented on a TMS320F28035-based controller, and the gating pulses generated are fed to the inverter switches through the gate-drive circuitry.

◀ **Figure 5.** Sub-harmonic oscillations observed in the simulated (a) q -axis stator current, (b) d -axis current, (c) R -phase stator current, (d) torque developed, and (e) rotor electric speed at the unstable equilibrium point A (shown in figure 4b). A $t_{dfsw} = 0.015$ is considered.

5.1 Sub-harmonic oscillations in the 11-kW drive

At the operating point A indicated in figure 4(b) (i.e. at $f_1 = 0.4$ pu and $V/f = 0.89$ pu), the measured R -phase stator current (trace 1), Y -phase stator current (trace 2) and dc bus voltage (trace 3) are as shown in figure 7. The measurements with SPWM scheme are shown in figure 7a, while those with CSVPWM are shown in figure 7b. Sub-harmonic oscillations are observed in the current waveforms in figure 7, confirming the operating point A to be unstable. The dc bus voltage is also found to be oscillatory with a peak-peak voltage of about 25 V.

The measured stator currents and DC bus voltage at the operating point B in figure 4b, i.e. at $f_1 = 0.7$ pu and $V/f = 0.89$ pu, are shown in figure 8. The waveforms in figure 8a and figure 8b correspond to SPWM and CSVPWM schemes, respectively. No sub-harmonic oscillations are observed in the measured currents and DC bus voltage, indicating the operating point B to be stable.

5.2 Region of oscillatory behaviour

The oscillatory behaviour, if any, of the motor drive is examined experimentally at different V/f ratios. V/f ratios between 0.5 and 1 pu in steps of 0.1 pu are considered for the measurements. For each V/f ratio, the drive is operated at speeds ranging between 5 and 50 Hz (say in steps of 1 Hz) to identify the unstable operating points. Considering the SPWM scheme, the set of unstable operating points are identified experimentally, and are indicated on the V - f plane in figure 9a. Similarly, the region of oscillatory behaviour with CSVPWM is shown in figure 9b. Thus, if a drive exhibits oscillatory behaviour with SPWM scheme, it should be expected to exhibit such oscillatory behaviour with CSVPWM scheme as well. Further, the region of oscillatory behaviour is almost the same for the two methods. This should also be expected in the light of the theoretical knowledge that the magnitude of the error voltage vector [see Eq. (3)] is equal for the two methods.

The experimentally determined region of oscillatory behaviour (figure 9a and b) match reasonably well with the simulated (figure 6b) and analytically predicted (figure 4b) regions.

Experiments are also performed at an increased switching frequency of 8 kHz and for the same dead-time duration of 3 μ s (i.e. $t_{dfsw} = 0.024$) and dc bus voltage of 600 V. The regions of oscillatory behaviour at this switching frequency, considering SPWM and CSPWM are shown in figure 10a and b respectively.

Figure 6. Stable and unstable equilibrium points in the V - f plane for an 11-kW induction motor drive under no load, as observed from the time-domain simulation model, considering $V_{dc} = 600$ V and (a) $t_{dfsw} = 0.006$, (b) $t_{dfsw} = 0.015$ and (c) $t_{dfsw} = 0.024$.

(a)

(b)

Figure 7. Measured stator currents and DC bus voltage at unstable operating point A (see figure 4b). (a) Sine-triangle PWM and (b) conventional space vector PWM. Trace 1: R-phase stator current (10 A/div), Trace 2: Y-phase stator current (10 A/div), and Trace 3: DC bus voltage (25 V/div). Time scale: 25 ms/div.

These results are in reasonable agreement with the simulated (see figure 6c) and analytically predicted (see figure 4c) regions.

Minor deviations between the experimental and simulated results could be on account of a few factors such as device drops, device switching delays, variable switching transition slopes of the inverter output voltages and minimum on/off times, which are difficult to incorporate in simulation and analysis. Also, in the analysis and simulation, the dc voltage is assumed to be constant. However, in the experiments, the dc bus voltage is observed to oscillate at sub-harmonic frequencies. Modelling such dc-side dynamics would add to the model complexity. Despite ignoring such effects, the predictions of oscillatory behaviour by the improved small-signal model and simulation are in reasonable agreement with the experimental results.

5.3 Mitigation of oscillatory behaviour using dead-time compensation

These sub-harmonic oscillations could be mitigated to an extent by employing a simple dead-time compensation

(a)

(b)

Figure 8. Measured stator currents and DC bus voltage at stable operating point B (see figure 4b). (a) Sine-triangle PWM and (b) conventional space vector PWM. Trace 1: R-phase stator current (10 A/div), Trace 2: Y-phase stator current (10 A/div), and Trace 3: DC bus voltage (25 V/div). Time scale: 10 ms/div.

scheme [7, 13]. A square-wave compensating signal, dependent on the current polarity, is added to the ideal sinusoidal modulating signal to compensate for the dead-time error voltage [7, 13]. The measured waveforms with dead-time compensation at the operating point A in figure 4b (i.e. $f_1 = 20$ Hz and $V/f = 0.89$ pu) are shown in figure 11. As opposed to the oscillatory waveforms before compensation as shown in figure 7a, the current waveform after compensation in figure 11 does not show any sub-harmonic oscillations.

6. Discussion

The results in the previous sections establish the validity of the improved small-signal model in predicting light-load instability of the 11-kW induction motor drive. This same model has also been shown recently to be more accurate than the standard small-signal model in predicting the region of sub-harmonic oscillations in a 100-kW induction motor drive [9]. The two sets of results together establish the applicability of the improved small-signal model to motor drives of different power levels.

(a)

(a)

(b)

(b)

Figure 9. Experimentally observed set of stable and unstable equilibrium points in the V - f plane for an 11-kW induction motor drive under no load, considering (a) sine-triangle PWM (SPWM) and (b) conventional space vector PWM (CSVPWM). $V_{dc} = 600$ V; $f_{sw} = 5$ kHz; $t_d = 3$ μ s.

Figure 10. Experimentally observed set of stable and unstable equilibrium points in the V - f plane for an 11-kW induction motor drive under no load, considering (a) sine-triangle PWM (SPWM) and (b) conventional space vector PWM (CSVPWM). $V_{dc} = 600$ V; $f_{sw} = 8$ kHz; $t_d = 3$ μ s.

In the case of the 100-kW induction motor drive, the standard small-signal model is able to predict the sub-harmonic oscillations, but it is inaccurate in predicting only the region of oscillatory behaviour [9]. However, in case of the present 11-kW motor, the standard small-signal model is unable to even recognise or indicate possible sub-harmonic oscillations in the drive at certain realistic values of $t_d f_{sw}$. Thus, this case study of the 11-kW motor drive better demonstrates the importance of the improved small-signal model in predicting oscillatory behaviour in motor drives.

7. Conclusion

This paper investigates whether an 11-kW induction motor drive exhibits oscillatory behaviour and the region of such oscillatory behaviour. The motor drive is found to oscillate in low and medium speeds under no load. The region of oscillatory behaviour increases with the ratio of the dead-time to switching cycle time. The improved small-signal model is shown to be much more accurate than the standard small-signal model in predicting the region of oscillatory behaviour. The regions predicted by the improved model in different cases are confirmed by simulation and

Figure 11. Mitigation of sub-harmonic oscillations with dead-time compensation at a fundamental frequency of 20 Hz and a V/f ratio of 0.89 pu (i.e. operating point A). Trace 1: R-phase stator current (20 A/div), Trace 2: Current polarity detection logic indicative of compensating signal (2V/div) and Trace 3: v_{RY} line to line voltage (1000 V/div), Time scale: 50 ms/div.

experimental results. Further, the region of oscillatory behaviour has been shown to be almost the same with sine-triangle and conventional space vector modulation schemes.

Identifying the region of oscillatory behaviour could potentially help in improved design of the motor, or at least, in handling the problem. Dead-time compensation schemes [7, 12, 13, 18–21] and oscillation mitigation schemes [10, 22, 23] could mitigate these oscillations. Mitigation of these sub-harmonic oscillations using dead-time compensation is also demonstrated in this paper.

Appendix

The various constituent matrices used in the small-signal model are defined as follows:

$$\mathbf{L} = \begin{bmatrix} L_s & 0 & L_m & 0 \\ 0 & L_s & 0 & L_m \\ L_m & 0 & L_r' & 0 \\ 0 & L_m & 0 & L_r' \end{bmatrix}, \quad (9)$$

$$\lambda_{10} = \begin{bmatrix} 0 \\ 0 \\ -(L_m i_{ds0} + L_r' i_{dr0}) \\ (L_m i_{qs0} + L_r' i_{qr0}) \end{bmatrix} \quad \lambda_{20} = \begin{bmatrix} L_m i_{dr0}' \\ -L_m i_{qr0}' \\ -L_m i_{ds0} \\ L_m i_{qs0} \end{bmatrix}. \quad (10)$$

$$\mathbf{R}_{sr} = \begin{bmatrix} 0 & \omega_{s0} L_m \\ -\omega_{s0} L_m & 0 \end{bmatrix}, \quad (11)$$

$$\mathbf{R}_{rs} = \begin{bmatrix} 0 & (\omega_{s0} - \omega_{r0}) L_m \\ -(\omega_{s0} - \omega_{r0}) L_m & 0 \end{bmatrix}, \quad (12)$$

$$\mathbf{R}_{rr} = \begin{bmatrix} r_r' & (\omega_{s0} - \omega_{r0}) L_r' \\ -(\omega_{s0} - \omega_{r0}) L_r' & r_r' \end{bmatrix}. \quad (13)$$
